LIST OF ILLUSTRATIONS IN VOLUME LXIX.

	PAGE		PAGE
Hæmosporidia in Reptiles. Plate.....	Facing 1	Powder Blower for the Stomach. Five Illustrations....	445
Papilloma of Nasal Septum. Four Illustrations.....	7	Fluoroscopic Picture of the Stomach.....	446
Forceps for Anastomosis.....	8	Aortic Aneurysm. Three Illustrations.....	513-515
A Substitute for the Murphy Button. Three Illustrations.....	8, 9	Tertiary Syphilis. Four Illustrations.....	516
Sphygmographic Tracings in Pneumonia.....	17	Acromegaly. Seven Illustrations.....	518-520
Coxa Vara. Eleven Illustrations.....	74-80	Fungus of Cancer. Nine Illustrations.....	541-544
A New Ophthalmoscope.....	102	Foster's Modification of the Hagedorn Needle. Two Illustrations.....	547
Gummatous Periostitis and Osteitis. Three Illustrations.....	146, 147	Bottini's Operation. Seven Illustrations.....	590-593
Hydronephrosis.....	148	Instrument for Gastrodiaphany.....	623
<i>Bacillus tuberculosus</i> . Plate.....	Facing 148	Gastrodiaphany in the Infant. Two Diagrams.....	624, 625
Typhoid Fever. Six Charts.....	189-191	Phocomelia of the Humerus in Epilepsy. Two Illustrations.....	659, 660
Adenoid Forceps.....	210	Supra-arterial Epicardial Fibroid Nodules. Five Illustrations.....	685-688
Graduate Measure for Modified Milk.....	211	A Simple Inhaler. Two Illustrations.....	725
The X Ray in Diagnosis of Tuberculosis. Five Illustrations.....	221, 222	A Modified Siegle's Pneumatic Ear Speculum.....	726
Papilloma of the Nasal Cavity. Three Illustrations.....	230, 231	A Study of the Bovine Brain. Two Illustrations.....	735
Psychoneuroses.....	289	A Point in Transfusion.....	743
Four Weight Charts.....	293, 294	A Modified Chloroform Inhaler.....	762
Infant's Weight Chart. Full page.....	295	Mortality of United States Troops. Chart.....	807
Cerebral Tumor. Six Illustrations.....	361-365	Leather Cases for Obstetric Instruments. Two Illustrations.....	839
The Hands in Epilepsy. Six Illustrations.....	367	Trays for Asphyxiated Infants. Two Illustrations.....	840
A New Surgical Table. Six Illustrations.....	389, 391	Plan for Obstetric Case at Bedside.....	842
Musk for Eczema in Infants. Two Illustrations.....	435	Pregnancy Index Cards. Five Diagrams.....	842-844
Prevention of Deformity after Knee Excision. Four Illustrations.....	438	A Compound Microscope for Examining the Eye.....	852

PLATE II. Hemopodidia in Rectum.

two to three microns wide by twelve to twenty-two microns long. The whitish or hyaline body is finely granulated, with two larger highly refractive vacuoles. There may be three or as many as eight or ten vacuoles in one animal, yet there is no rule for their distribution except that nearly always a larger one can be distinguished both in the anterior and posterior half of the body, the others being unevenly scattered—in fact, moving to and fro with the general movement of the body. The pointed extremity always floats foremost; it may also attach itself to some casual obstacle in the plasma, but the posterior end does so as a rule. Other lively movements are not rare. Besides floating between the blood-cells the parasites bend and unbend one third of their length like a pocket knife, double themselves up to a ring and straighten again, or, after attaching the thicker end to a blood-cell, swing for minutes in a circle or drag along the cell to which they are anchored (Fig. 2). I have never seen the animal pierce a blood-cell, a feature which is described as of frequent occurrence in *Drepanidium iranarum*. Their speed varies much. They may rest in one spot for a long time or pass the length of an erythrocyte—i. e., about twenty microns—in three seconds. While they are floating along another peculiar motion is sometimes seen, a symmetrical indentation or annular constriction running from the anterior to the posterior end. A new constriction may commence before the first one has run off, thus giving a beaded outline (Fig. 3). The forward movement is not accelerated in this way—in fact, it is evident that this motion serves only to mix or shake up the constituents of the endoplasm. Sometimes the constriction is arrested at one spot for a longer time, the animal turning on the pivot to all sides as if it would break off; suddenly, however, the constriction glides slowly off to the posterior end. True amoeboid movements are not met with, although the posterior end sometimes contracts and bulges out to such an extent that the whole animal presents the shape of an ampulla, the anterior end simulating a pseudopodium (Fig. 4).

In the fresh, unstained specimen the nucleus is not easily discerned. In many cases, however, one can see an ovoid spot near the middle about a fourth of the size of the animal. It is seen bulging out when the parasite happens to lie on its side. The nucleus appears as a lighter reddish spot with indistinct outlines, or as a clump of larger granules when the animal is dead. In some cases none but freely moving organisms can be detected; in the majority, however, both free and intracellular forms are found. Of the intracellular structures two types are to be distinguished: a long and slender one and a shorter one, rounded at each extremity, of bean or kidney shape (Fig. 6). This is due to the folding of its pointed end again to its body. The vacuoles and nucleus are plainly visible as in the free form. In the fresh blood the animal fills its intracorporeal space completely, but in the smear after fixation a white peripheral

rim surrounds the animal more or less. This is an artifact produced by the contraction of the body in the fixing reagents. The shrinkage is sometimes avoided by rapid fixation of the fresh smear in Lang's fluid. The intracorporeal organisms, as a rule, lie quiet, yet at times they move slowly inside the cell. Once the erythrocyte was violently distorted for ten minutes to all possible shapes without breaking. I have never witnessed a rupture of the cell. They are not affected in the least by heating on a warming stage, though at the same time the free ones are rather more lively and the leucocytes show great activity. The parasites are very tenacious of life and retain their form long after death. Even after two days they exhibit slow movement in the hanging drop, and when, after a week or more, the blood-corpuseles are entirely disintegrated or appear as mere shadows, the outlines and details of the hemosporidia are still plainly visible. The parasites may survive their host for a long time—e. g., a frog showed signs of advanced decay and still the animalcules were quite lively in the plasma. No pigment was ever found in the organisms.

In the dried and stained specimen the free parasites are easily recognized if they retain their original shape (Fig. 1, f). More often they bend just before the film of the smear dries (Fig. 5). The two varieties of the intracorporeal hemosporidia—the long and narrow one slightly curved, and the shorter stout one of kidney shape—are also better distinguished than during life. Both may occur in the same blood, but one variety generally predominates (photographs A and B). In the slender form the chromatic substance is scattered in fine dustlike granules all over the length of the parasite; it is amphiphilic, staining both with eosin and methylene blue. The short types are sometimes almost devoid of it, or larger masses of chromatic granules are grouped toward both ends (Figs. 8 and 10). The long organism is either stretched out to its full length or merely the tip curved in. In the short one the curved-in outline is mostly obliterated; many, however, still show clearly that about one third of the whole length is bent toward the body. Hence, the nucleus, which otherwise would be in the middle, is placed near one end.

The appearance of the nucleus varies considerably. In the slender form it consists of an elongated oval clump of fine chromatin granules. In the stout form it may be an ovoid, slightly staining area, the rest of the organism taking a deep stain; or it is a dense mass of heavy chromatin granules, which give it the appearance of a square cross band (photograph B). In other instances the chromatin is arranged in filaments like a spireme in mitosis, or opposite threads stand at right angles to the long axis of the parasite (Fig. 10). Labbé describes caryocinesis as occurring in the hemosporidia. The figures found by myself can not be claimed to be typical examples of caryocinesis; nevertheless, they recur with such regularity in these slides in which nearly all

the parasites have reached the same stage of maturity as to seem to be of significance (Fig. 10).

The intracellular parasite is, as a rule, completely surrounded by the cytoplasm. Occasionally one end or both ends protrude from the outlines of the blood-cell. In most cases the infected blood-cell contains but one parasite, but in many two are present, which are usually of the same age or seldom of different size. In some slides there are as many double inclusions as single ones. In rare exceptions three hæmosporidia are found in a single blood-cell. The number of the parasites varies extremely. There may be found two or three infected blood-cells in a whole slide, while in other slides every third erythrocyte may contain a hæmatozoon. An instance of the latter condition occurred in a copperhead of North Carolina of a size somewhat below the average (twenty-four inches). Danilewsky found more parasites in his turtles the older the animal. This observation is not confirmed in my snakes. The moccasins, which on account of their number and universal infection present the best objects of comparison, generally showed fewer hæmosporidia the older the host.

The erythrocytes react differently toward the parasites. At times a simple elongation or a rounding off or a slight distortion is effected. Often, however, the parasite does not seem to exert any influence at all; both hæmoglobin and nucleus stain as they do in the normal cell (Figs. 6 and 7). This condition may remain unaltered for a long time, and even after the parasite has emerged from the cell its remaining fragments stain normally. At other times the hæmoglobin is gradually absorbed, the decolorized and not distended stroma remaining, or the erythrocyte is enlarged to two or three times its normal size; the hæmoglobin stains faintly, fading off halo-like into its surroundings (Fig. 8). Or, hæmoglobin and stroma are absorbed alike, a trace of the latter with the adherent nucleus being attached to the hæmosporidium. Another remarkable behavior of the hæmoglobin was seen in the blood-cells of a ribbon snake. The erythrocyte of normal size had a colorless peripheral zone surrounding an area of normal hæmoglobin which enveloped both nucleus and parasite (Fig. 9). Excepting a displacement to one side or to one extremity of the blood-cell, some mechanical pressure, as elongation or flattening, the nucleus remained unchanged, this even after the cell had lost its hæmoglobin or had been entirely absorbed. Very seldom a cell is found the nucleus of which is enlarged to double its normal size, showing no sign of disintegration. In a single instance in a copperhead the nuclei of several erythrocytes were directly invaded by the parasites and considerably enlarged. Thus far no infected leucocyte has been found.

These varying conditions of the erythrocyte are not deemed to be of great import, yet they have been detailed because some writers incline to use even such trifles for purposes of classification. For this reason it may be said that, though one type or other predominates

in the respective species of snakes, all types are found more or less promiscuously. The different reactions of the blood-cell may be partially explained by the diversities of the hæmoglobin. Since its variability in warm-blooded animals even of the same order is so well known, it is not illogical to assume a similar condition in cold-blooded animals.* Most observers have laid little stress upon the substratum on which these parasites are living. It is improbable that the blood of the different species or orders of animals should react exactly alike, and at least some biological diversities might thus be accounted for—e. g., *Hamamaba subimmaculata* (Grassi and Foletti), which was found in a single individual of falcon, is distinguished from its nearest relations only by the lack of pigment.

Now the question of a capsule arises. Doubtless the first impression given by the presence of the white rim is that of a capsule; nevertheless, it is evident that the parasite is lying in a mere gap of the surrounding protoplasm. Whenever a crescent-shaped hæmosporidium seems to float freely in the plasma, it is barely possible to trace some very faint remnants of the stroma of the destroyed blood-cell; its nucleus is nearly always found adherent to the parasite by some hidden bond. A similar figure is produced when the free hæmosporidia fold themselves the instant the film of the smear is drying. The organism shrinks as described above, and the faintly staining plasma forms exactly the same bean-shaped inclosure which we encounter so distinctly in the erythrocytes (Fig. 5). An instantaneous production of a capsule is certainly an impossibility.

All observers agree that the development of the hæmosporidia in cold-blooded animals is extremely slow. The ophidian hæmosporidia are no exception to this rule. Neither a careful watching of a hanging drop for about a week, with occasional warming, nor the examination of the same blood, several days, weeks, or months intervening, showed an appreciable change. It has not been my good fortune to follow up a complete cycle of development, so that on this point I have only a few disconnected facts to offer. In the blood of a moccasin which, to my regret, was not taken before death, some of the numerous intracellular parasites exhibit the mitotic figures described above, but not so distinctly as in some other preparations. Later, in the place of the nucleus in many parasites a roundish disc of three to four microns in diameter appears. It stains palely with methylene blue, with a much darker rim. The rest of the organism is filled with a colorless granular mass of blue granules (cf. Plate plate graph. CV). The discs, having been extruded from the cells into the plasma, where they enlarge somewhat to a diameter of ten microns in diameter. Some of these discs are

* It may be mentioned here that the hæmoglobin of the cold-blooded animals is not so variable as that of the warm-blooded animals. The hæmoglobin of the cold-blooded animals is not so variable as that of the warm-blooded animals. The hæmoglobin of the cold-blooded animals is not so variable as that of the warm-blooded animals.

scattered across the pale central surface (Fig. 12). Whether these bodies undergo segmentation in the circulating blood or are previously carried to some internal organ, I am unable to say. By examination of fresh liver and kidney and in the numerous sections of kidney, liver, and spleen nothing was found, except in a single preparation of a moccasin liver, in which two bodies were seen which are apparently sporocysts, of about fourteen by seventeen microns, with numerous tiny spores. The bone marrow, for which the only available place would be the vertebrae, has not been investigated.* In the same blood were small roundish or fusiform bodies, highly refractive in the centre and staining with a blue rim, about three by five microns. Some of them adhere closely to a blood-cell, causing a deep inflection, as if in the act of penetrating (Fig. 13). The same bodies are seen inside some erythrocytes, where they assume also a circular or indented shape. As they grow, a minute crescent-shaped parasite of the described nature, with a tiny nucleus, will be seen (Fig. 14). According to the investigations of Labbé, who alone thus far has been able to follow up the complete process of development, the animals, after reaching a certain stage inside of the blood-cell, live for a while in the plasma to copulate there and reenter the blood-corpuscles for maturing. I am inclined to think that the slender intracellular parasite, which exhibits no bending, represents the first stage, that its size somewhat increases in the plasma, so that on reentering the blood-cell it has to adapt itself to the small house by bending a part of its body. The plica of the interior curve is obliterated, leaving an apparently smooth, bean-shaped body which is ready for further maturation.

An observation of great importance was made in a single instance in the blood of the West Indian tree boa. The fresh blood exhibited numerous short intracorpuseular, but still more freely moving parasites of extraordinary activity. A hanging drop was laid aside and examined again eighteen hours later. There were still living haemosporidia, but on the margin of the drop there were found two forms of *Polymilus*, one a spherical reddish body with five buds, the other with six buds and two long, colorless flagella (Fig. 15), the latter provided with the well-known olive-shaped swellings. No granules of pigment were seen. They were motionless and had disappeared the following day. This type of structure has thus far been observed only in the gymnosporidia (Labbé), the blood parasites of birds, and of human malaria. Its real nature has been a riddle to all investigators; most observers proclaim them a phase of degeneration, and until recently MacCallum attributed to them a fertilizing function. According to his researches, the flagella break off from the central sphere, whirl around in the plasma, and penetrate another similar granulated body. Whatever the correct explanation

of these organisms may be, their coincidence with the haemosporidia of cold-blooded animals either tends to prove that such a mode of propagation exists in a larger number of related species than has been hitherto believed, or it establishes a near relationship between the orders of *Hemosporidia* and *Acystosporidia*, which have been of late separated by Labbé. In tracing the possible origin of the haemosporidia it must be remembered that most of the writers consider the intestinal canal to be the port of infection. Danilewsky, in his very first publication (*Biolog. Centralbl.*, 1885), pronounces this the most probable. It is surely interesting that the most recent paper of MacCallum not only supports the same hypothesis, but also proves by the microscope the presence of an abundance of so-called pseudo-vermiculi—*i. e.*, of the motile extracellular types—in the contents of the intestines and in the cells of the intestinal walls.

In the snakes examined it is evident that the aquatic species exhibit the largest percentage of infection. The frog has been known for years as the first and only host to harbor these parasites. Moccasin snakes live almost exclusively on batrachians and fish; only in later years do they also partake of warm-blooded animals, mostly rodents. All the other species found infected live either on frogs, as is the case with the water, garter, and ribbon snakes, or on other snakes and lizards, which is the case with the king, gopher, and coral snakes. The copperhead feeds on wood frogs (*Rana silvatica*), birds, and other snakes; the prairie rattler, so far as known, only on rodents and birds, but in his desert home he undoubtedly does not despise an occasional lizard. The diamond-back and the banded rattler eat only warm-blooded animals. It must be admitted that most of the snakes are exposed to the same noxious influences which may infect a frog, but the food habits of the different species seem to point strongly to the intestinal canal as the road of entrance for the infection. The faces of the snakes have been frequently examined for haemosporidia or their like, and, while snakes are infested by an amazing amount and variety of entozoa, the eggs of which were often seen, no trace of haemosporidia was discovered.

Hence the search for the presence of haemosporidia in American batrachians, of which to my knowledge no record exists, suggested itself. The frogs of the neighborhood of New York are not often affected—perhaps one in five of those examined. Frogs from North Carolina, however, were in greater percentage, and those from Florida were nearly all invaded by blood parasites. The same ratio of infection was found in a number of frogs high up in the Adirondack Mountains; these were all taken from a swampy expansion of the Ausable River. The parasites of the frogs were to all appearances exactly the same as those of the snakes, except that in some frogs their size was below the average. In nearly all of the Southern frogs the flagellate *Trypanosoma* was present in varying abundance. These facts

* The bone marrow of an infected frog gave no result.

lend added strength to the hypothesis of a spread of infection in the snake through its food.

An interesting type of parasite occurred in two frogs from the neighborhood of New York, one each from Long Island and Staten Island. Its morphology and the distribution of vacuoles correspond with those described previously; in size, however, it was larger—more than twenty microns long by about seven or eight microns wide—and it moved with the thicker end forward (Fig. 17). Of vacuoles there were always more than two; the nucleus was easily distinguished and the cross stripes of the myocyte were sometimes visible. The most remarkable difference lies in the behavior of the invaded blood-cell. As soon as a small organism has entered the cell the nucleus reacts, as a rule, at once by a considerable enlargement to more than double its former size (Fig. 16). As the parasite grows the erythrocyte enlarges slightly, but the hæmoglobin remains unchanged, staining as in a normal cell. Nevertheless, as the haemosporidium stretches out so that its length exceeds the diameter of the cell, it folds in to accommodate itself to the interior. In the meantime the blood-cell nucleus has broken up into two, three, or innumerable fragments, which are pushed to one side or are scattered all over the cell (photograph D). Occasionally, though very rarely, a blood-cell is found the stroma of which is breaking up, while the enlarged nucleus remains entire. The body of the large intracellular organism sometimes, but seldom, shows a nucleus. One of these frogs had in its faeces very similar but smaller organisms with a single reddish vacuole and decidedly amoeboid movement, together with an immense number of some coccidian sporocysts which sporulated freely.

With the exception of the last type described, all the organisms found in the different snakes, the turtles, and the frogs seem to be materially the same. Of all the turtles examined, the species *Chrysemys* alone was infected. This may be explained by the circumstance that most of the other specimens were younger than those of *Chrysemys*.

Any one familiar with the blood parasites in question will agree that the species described resemble the one named *Drepanidium ranarum* by Lankester, discovered in turtles and named *Harmogregarina Stepanovi* by Danilewsky, *Drepanidium princeps* by Labbé. Great emphasis is laid in classification on the nucleus and the vacuoles. How much these may differ even in the same individual I have tried to show. The annular constrictions which prompted Labbé to establish a new species, *Drepanidium monilis*, were seen occasionally by me in the living and moving parasites, while others in the same preparation were gliding along without contraction. An absolutely reliable classification is rendered possible only by the observation of the development. So long as this is wanting in the majority of these animals we ought to refrain from finding a new species in every new host.

For the same reason I would assign the second species described in this paper also to the species *Drepanidium*, perhaps *Drepanidium magnum* (Kruse). Its most striking influence upon the blood-cells is caryolytic; it differs, however, widely from the organism called by Labbé *Karyolysus lacertarum*. According to his observations, it never exceeds the length of the blood-cell and does not destroy the nucleus except after the previous disintegration of the erythrocyte. Whether the changes observed in the two frogs entitle us to make a new *Karyolysus ranarum*, or at least a *Drepanidium karyolyticum*, which may act somewhat differently in frogs and in lizards, will depend upon further investigation.

The question has been raised whether the parasites are pathogenic for their host. A decision of this point is now impossible, although the presence of a parasite in every four or three blood-cells would presumably be not without deleterious effect. The pathological changes, if any, in the internal organs have not been followed up. Most of the snakes kept in captivity perish from the so-called canker of the mouth, a disease dreaded by all keepers of zoological collections. It is a diphtherialike membranous affection, commonly associated with and perhaps caused by a coccus, which is now under investigation. It was first thought that the blood disease might somewhat influence the affection of the mouth, but such was not the case. On the contrary, rattlesnakes which are exempt from haemosporidian invasion succumb mostly to the mouth disease. The experience related above—namely, that the older moccasins show generally less severe infection than the younger ones—points to the possibility of an elimination or to a self-limited existence of the parasite.

Inoculation from animal to animal of the same or a different species has been attempted by a number of investigators, but with little success. My own inoculations have been done from snake to snake, to frog and to newt; and from frog to frog, etc. Fresh blood was injected into the lymph sac, peritoneum, and intravenously; infected liver was also fed, i. e., pushed down into the stomach. All the experiments were without positive result. It is not unlikely that the frequent failures reported are due to the slow development of the parasites. *A priori* we ought to expect a ready transfer by the infected blood corpuscles, as it is well known that they are quickly dissolved in the plasma of another host even of the same species. The parasites liberated in this way ought to spread rapidly through the circulatory system of the new host. Unless, however, they have the proper state of maturity at the time of the inoculation they will be deprived of their protective envelope, only to perish so much sooner. On the other hand, even after a successful inoculation, we are liable to find no parasites before we can decide what our experiments are to prove. These difficulties in the way of a successful transmission do not apply exactly to the experiments on

birds and men, since the development there is so much more rapid; yet it may be all-important also in this case to select the most propitious time.

I may summarize the results of my investigations in the following conclusions:

1. Infection by hæmosporidia is not rare in American snakes, harmless as well as poisonous.
2. The aquatic species are more prone to such infection.
3. The species of parasites do not differ materially from those known in other cold-blooded animals.
4. A species of caryolytic drepanidium seems to exist in frogs.
5. The type of *Polymitus* thus far observed only in hæmatozoan infection of birds and men occurs also with the hæmosporidia of reptiles.

I can not conclude without thanking Dr. A. V. Moschowitz for material and untiring assistance in the foregoing researches. To Dr. T. M. Prudden I am indebted for many courtesies and valuable advice during the pursuit of my work, also to Dr. Edward Leaming for the careful and painstaking execution of the photographs.

DESCRIPTION OF THE ILLUSTRATIONS.

The figures have partly been drawn with camera lucida. The size has been arbitrarily enlarged. Zeiss $\frac{1}{2}$, ocular 1, has been about doubled for more distinct illustration. The photomicrographs with Zeiss's apochromatic are $\frac{1}{1000}$.

Figs. 1 to 6 represent the living forms of parasites.

1. Free parasites in their usual outline.
2. Free parasites bending in different shapes.
3. Free parasites with annular constrictions.
4. Free parasites forming ampulla.
5. Curved form in surrounding plasma, simulating a capsule.
6. Living forms in red blood-corpuscle.
7. Slender intracorpuseular form, stained. Moccasin's blood.
8. Short, bean-shaped form, the erythrocyte dissolving. Prairie rattler's blood.
9. Peripheral decoloration of erythrocyte. Ribbon snake.
10. Mitotic figures in short type of intracorpuseular parasite. Moccasin's blood.
11. Formation of round disc in the parasite of preceding type.
12. Discs extruded, floating freely in plasma.
13. Spore penetrating a red blood-cell.
14. Three different aspects of intracorpuseular spore.
15. Two specimens of *Polymitus*. West Indian tree boa.
16. Frog's blood. Enlargement of nucleus after invasion of small parasite.
17. Frog's blood. Large extracellular parasite with cross stripes of myocyte.
- A. Slender form of intracorpuseular parasite; one free in plasma. Moccasin's blood. The cross stripes of the blood cells are the effect of shrinking.
- B. Short form of intracorpuseular parasite. Moccasin's blood.

- C. Formation of disc in intracorpuseular parasite. One free spore and one free disc. Moccasin's blood.
- D. Caryolytic parasite in frog's blood.

PAPILLOMA OF NASAL SÆPTUM.*

By BEAMAN DOUGLASS, M.D.,

PATHOLOGIST AND ASSISTANT SURGEON,
MANHATTAN EYE AND EAR HOSPITAL (ORBIT DEPARTMENT);
INSTRUCTOR IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL, ETC.

THE object of this paper is to establish in full the history, condition, and examination of a patient having a true papilloma of the nose, and to present a specimen with photomicrographic views of the tumor removed from the nose.

Mrs. V., aged sixty-four, applied at my office for relief of a right-sided nasal obstruction. She stated that she had been for four years conscious that something occluded the right nares. The occlusion was partial and constant, and was not greater at night than in the daytime. There were no other symptoms.

Examination disclosed a warty growth located on the mucous membrane of the right side of the nasal septum and behind the tubercle of the septum. This warty growth partially filled the inferior meatus, causing some obstruction to inspiration more than expiration. The growth was not ulcerated, and no enlarged vessels were seen.

After cocaineization the snare removed the growth; the base was treated with chromic acid, a dusting powder was prescribed for home treatment, and the wound healed in one week.

This patient has been seen from time to time since the removal, now one year ago, and the nose presents a normal appearance. The obstruction symptoms were relieved. The family history of this case showed no syphilis, cancer, or tuberculosis either in the patient, her ancestors, or her children. She is of robust frame, somewhat given to rheumatic conditions, indigestion, and cardiac palpitation from gastric causes. Her menstrual life was normal and ceased in the usual way without difficulty. There are no papillary growths on the patient's skin.

Examination.—In the right naris, at the inferior meatus, behind the tuberculum septi, and springing from the septum, is a warty tumor three quarters of an inch in diameter, irregularly rounded, with rather a broad base, slightly pedunculated. The tumor contracted one third in bulk under cocaine (four-per-cent.) solution, and after removal and hardening in alcohol shrunk three quarters of its original bulk.

* Read before the Laryngological Section of the New York Academy of Medicine, October 27, 1898.

Sections were made in the usual way, and stained with hæmatoxylin and carmin. Macroscopically the sections appeared to be formed of two layers, an outward epithelial and deeply stained layer surrounding another less deeply stained interstitial layer. This inner layer was divided very frequently into branches,

FIG. 1.—Magnified 40 diameters.

which, like the branches of a tree, never reunited, but remained free. Each part of the interstitial layer was surrounded on all sides by a greatly thickened epithelial layer.

Examined with a No. 4 eyepiece and No. 4 objective, Leitz, the appearances macroscopically were confirmed

FIG. 2.—Magnified 100 diameters.

and the much thickened epithelial layer was found composed of large squamous epithelial cells, which became smaller and more compact as they approached the interstitial tissue. The central tissue, comprising the part called the interstitial tissue, was made up of fibrous

connective tissue, with long, spindle, connective-tissue cells and a few blood-vessels. No glands were found. The connective tissue was very scanty in proportion to the quantity of epithelium present.

This connective tissue and the epithelial cells we see are arranged in numerous papillae, each papilla having for a centre the scanty connective tissue, with per-

FIG. 3.—Magnified 15 diameters.

haps a small blood-vessel, and outside this layer upon layer of squamous epithelial cells. These papillae extend in every direction, and are always separate. The appearance is shown in the photomicrograph.

It is clear that the tumor is a form of true nasal papilloma, and can not be confounded with the de-

FIG. 4.—Micrograph.

scriptions of nasal papilloma. It was first found by the observer to whom I refer.

Later investigations have shown that the same data described by Heidenreich in 1887, and by others, are papilloma at all times.

gland tissue, a fibrous stroma infiltrated with leucocytes, and some interspace exudation (redema) in the fibrous stroma, and outside this structure columnar epithelial cells arranged regularly as in an ordinary mucous membrane.

This form of tumor—Hopmann's polyp, as it is now called—is the ordinary polyp process of mucous membrane which has become folded and convoluted and furrowed because of the pressure to which it has been subjected in the limited space in which it grew. If an ordinary polyp (fibroma oedematose) has filled the space and continues to grow, it *must* fold upon itself and produce the form of growth as described by Hopmann.

In an excellent paper on Nasal Papillomata, by Dr. Jonathan Wright (*New York Medical Journal*, December 26, 1891), this difference is pointed out clearly, and an illustration of a papilloma such as is described by Hopmann is shown. Dr. Wright here demonstrates that such growths can only be the ordinary polyp formation which has, from pressure, taken on a false papillomatous appearance. Dr. Wright says: "It is impossible to say how many cases of true nasal papillomata have been observed. Doubtless some of those so reported were not papillary fibromata. It is certain that only those which have been examined microscopically can be accurately classified, though some had every macroscopic appearance of a true papilloma. They evidently have a preference for the cartilaginous septum and the floor of the nose, while Hopmann's growths are more frequently found on the turbinated bones, especially the inferior—the most frequent site of hypertrophies."

Virehow says that "the pathological importance of papillary tumor is, at least so far as I know, determined by the condition of the basement substance or by that of the parenchyma of the villi themselves."

If this be so—and we all willingly bend to the dictum of the father of pathology—it is evident that the papillomata described by Hopmann are not of this class, but belong to the ordinary hypertrophies of mucous membrane which have undergone some pressure effects; while the description of a papilloma of the vocal cords will stand as an example of a true papilloma. The structure of the tumor described in this paper is exactly the same as that which describes a papilloma of the vocal cord. This specimen, then, is a true *papillary fibroma* of the nasal septum.

A SUBSTITUTE FOR THE MURPHY BUTTON.

By LOUIS A. GENELLA, M.D.,
NEW ORLEANS.

As allurgeon know, the principal drawback to the majority of instrument is the exorbitant price asked for them. Let them contain a hinge or a bolt and immediately a small fortune is charged for them. So, any in-

strument that is easy to make and easy to sterilize is, in my opinion, a great improvement on an otherwise complicated piece of mechanism containing numerous hollows and hinges for the harboring of bacteria during the process of sterilization. The instrument I offer as a substitute for Murphy's button, for intestinal anastomosis, is easy to make and easy to apply and easy to sterilize. The instrument consists of but two blades of forceps. Both blades are of the same size and structure, except, as in other forceps, one is a female and the other a male blade, for disarticulation and sterilization.

FIG. 1.

The opening at A' and A'' should be about an eighth of an inch. Both blades are triangular down to B' and B'' to give strength. The rest of the handles and the incomplete circular blades are round—about a fifth of an inch in diameter. When fixed in position the instrument is locked at D' and D'' and fixed or clasped at C' and C'', as any artery forceps.

The *modus operandi* of the operation is as follows:

Open the abdomen as usual and remove the portion

FIG. 2.

of the intestine diseased or injured. Then about a third of an inch from the cut margin of the gut, at a point opposite the mesenteric attachment, puncture a hole or cut a slit a fifth of an inch. An ordinary aspirating needle is the best instrument to use.

Now take either male or female blade, and holding

handle down, insert the end of the incomplete circular end of the blade into the hole and by a circular motion, raising the handle up always, you place the incomplete circular handle inside the gut. Then insert the other blade in the other gut in exactly the same way.

FIG. 3.

The above is a picture of both blades in place. Now invaginate the ends of each gut in upon the ring of the forceps, lock the blades, and clasp, care being taken not to clasp them too tight for fear of injuring the gut. Often the gut, after being invaginated, refuses to remain long enough to allow you to lock and clasp the forceps. In that case, which is apt to arise when assistance is not readily obtained, or is limited, all you have to do is to insert the two primary stitches of Monsel's (invaginating operation with his fenestra). But instead of using his window just thread the stitches on a needle and pass them through the fifth-of-an-inch puncture next to the handle of the male blade. Now pull on your stitches and invaginate the guts until you have your blades firmly locked. Then pull on one end of your stitch and you can remove both, as they no longer serve a useful purpose.

FIG. 4.

The cut shows the appearance of the forceps after being placed, locked, and clasped.

Note the slight turn of the forceps at H, to guard against pinching the gut too tight and to insure even pressure. Insert and tie all around the gut a row of Lambert sutures at will, ten or twenty if desired. I enclose your forceps until it no longer holds the cut. Do not open it more than very slightly, for one must remember not to tear the gut.

Now bring the handles of the forceps down again through the hole in the mesentery, and up again; so by this circle you can remove the forceps from the intestinal tract.

Next carefully stitch up the fenestra in the mesentery and the two little fifth-of-an-inch puncture holes, and you have finished a simple anastomosis and have left nothing foreign in the intestines.

This operation is superior to Murphy's in that no irritating body is left in the intestinal tract. The instrument is simple and inexpensive, and can be easily sterilized.

It is superior to Monsel's invagination in substituting a fenestra a fifth of an inch in diameter for his fenestra of an inch or an inch and a half. And the Lambert sutures can be made firmer and more regular, without having the gut constantly slipping away.

This instrument is superior to La Place's modification of Dr. Murphy's, in that it is simpler and easier to clean. In all other points Dr. La Place's is just as good.

The only point to be careful of is not to pinch the gut, and not to open the blades too wide when you wish to remove them. Do not stitch the cut in the mesentery until the forceps is removed.

In the operation some little points of standard usage I have omitted purposely to economize space.

THE DIAGNOSIS AND TREATMENT OF THE MORE COMMON BLADDER AFFECTIONS IN WOMEN BY MEANS OF KELLY'S METHOD.*

By HIRAM N. VINEBERG, M.D.,
ATTENDING GYNECOLOGIST TO ST. MARK'S HOSPITAL,
AND TO MOUNT SINAI HOSPITAL, OUTDOOR DEPARTMENT.

So brilliant is the work Howard A. Kelly has done in the upper urinary passages that the value of his method in the diagnosis and treatment of the diseases of the bladder has not yet met with the appreciation and recognition it deserves.

For instance, in quite a recent article in the *Journal of American Obstetrics* (March, 1897), by Skene, the American Nestor of bladder surgery in women, the use of the cystoscope is recommended almost as a *dernier ressort*, when everything else has been tried and has failed. Let us quote Skene's own words on this point: "The objections to the general employment of Kelly's method are that rapid and extensive dilatation of the urethra is necessary, and that requires the patient to be anaesthetized. Taken altogether, it makes the examination really a formidable operation. Dilatation of the normal urethra is an enterprise that is not undertaken by the majority of gynecologists." The author then proceeds to describe his own method, which is a modification of Kelly's.

* REPRODUCED BY PERMISSION OF THE PUBLISHERS, THE N. Y. A. Academy of MEDICAL SCIENCE, 1900.

me how any one familiar with the method could speak of it in those terms.

As the subject matter of this paper is presented, it will be seen that general anaesthesia is rarely necessary—only once so far in the writer's experience, and that was at a time when he was still unfamiliar with the method—and that extensive dilatation of the urethra is never called for.

During the three years that I have been employing Kelly's method I have made use of the cystoscope fully five hundred times in over one hundred different women,* and I can positively assert that in not a single instance was any appreciable harm done to the urethra. The size of the cystoscope used in the vast majority of cases was that known as No. 10. Very rarely was No. 12 necessary, and No. 8 frequently served the purpose. I have never observed incontinence, even of a temporary duration, follow the introduction of the No. 12 cystoscope, and, as I have already stated, I have never had occasion to use a larger sized instrument. Even for the catheterism of the ureters I seldom use a larger cystoscope than the No. 10, and in the numerous times that I have carried out the procedure I have not thus far had to use general anaesthesia once.

To illustrate how expeditiously direct inspection of the bladder and catheterism of the ureters can be done after one has had some practice, I will cite only one example.

Last January a lady came during the office hours with a note from my friend, Dr. M. Manges, asking that I obtain for him a specimen of urine from each kidney. She was a short, stout woman, about fifty years of age, and of a nervous and anxious temperament. She never had had a similar examination and was in no way prepared for it. From the time she entered my office until she left it, with two small bottles of urine from either kidney, obtained by catheterism of both ureters, about thirty minutes elapsed. She suffered some pain for about twenty-four hours as a result of the examination, and this was the only ill effect that followed.

It may be appropriate here to say a word relative to the propriety of attaching Kelly's name to the method of direct visual inspection of the bladder as it is practiced in this country. Without desiring to enter into a discussion as to claims of priority, so much may be safely asserted, that Kelly has so simplified the technique that it becomes one distinctly apart from that practiced in Germany. No better evidence can be needed than the fact that Volz's *Handbuch der Gynäkologie*,† the most recent and authoritative work on gynecology in the German language. The article on the physical examination of the bladder is so extensive, and is chiefly

devoted to the use of Nitze's cystoscope.* It is not possible to conceive how any person who was ever familiar with a method similar to that which Kelly has introduced into this country would waste his time in describing at length so complicated a method as cystoscopy in women either with the Nitze or the Casper instrument. In Kelly's method you have simple instruments, easily sterilized, the use of which is readily learned. You inspect the object directly, and you have a hollow tube through which you may make a direct application to the bladder and pass a catheter into either ureter with the greatest ease.

In Nitze's or Casper's method you have a complicated and extensive instrument not capable of perfect sterilization, the use of which requires very long practice; you have to view the object through the medium of a fluid, and you have no means whereby you may make a direct application to the interior of the bladder.

Being once provided with the necessary instruments, an ocular examination of the bladder in women by Kelly's method becomes as easy a matter as the use of the laryngoscope, and can be just as readily learned. I grant that the exposure of the ureteral orifices and the introduction of a catheter into the ureters requires considerable practice before one becomes an adept at it, but the cases calling for such an examination are comparatively few in number and will always belong to the domain of the expert.

Kelly's cystoscopes have been so frequently described and are generally so well known that I may leave out their description here. A few practical points regarding the technique, however, may not be amiss.

The patient loosens all the clothing about the waist, and is first placed on the table in the lithotomy position. A small glass catheter is introduced into the bladder and the urine withdrawn and kept for examination if necessary. The bladder is then injected with a one-per-cent. solution of boric acid by attaching the rubber tubing of a graduated glass irrigator to the catheter and allowing about from six to eight ounces of the solution to flow into the bladder; the rubber tubing is then detached, and the solution escapes from the bladder through the glass catheter, which has remained *in situ* all the time. This manoeuvre is repeated until the returning fluid is quite clear. Then, with a short, flexible catheter attached to a small glass syringe, four cubic centimetres (one drachm) of a four-per-cent. solution of cocaine is thrown into the bladder, some of the solution being injected into the urethra by withdrawing the catheter before the syringe is completely emptied. A pledget of cotton soaked in a ten-per-cent. solution of cocaine is introduced into the meatus and left there.

The patient is now placed in the knee-chest position, the pledget of cotton is removed from the meatus, and

* It is not possible to state the number of different women examined. A large number of the women suffer from bladder trouble, and the examination is intended to be a routine and repeated in the future. It is not possible to state the number of times until the symptoms are relieved.

† Volz, 1901, p. 172.

Physikalische Untersuchungsverfahren der Harn-Blase, vol. II, pp. 172-173. Volz's *Handbuch der Gynäkologie*.

a No. 8 or No. 10 vesical speculum is introduced into the bladder and the obturator is withdrawn. It is seldom necessary to dilate the urethra prior to using specula of that size. Occasionally, however, in elderly women with marked atrophy of the external genitals, the meatus is very much constricted and unyielding, and it may be necessary to snip with scissors the posterior lip of the meatus before a speculum of that calibre can be introduced. I have always employed a small electric headlight for my examinations, but an Argand burner, or a candle even, properly placed, with a head mirror similar to that used by laryngologists, will give the required illumination.

It is scarcely necessary to say that the strictest aseptic precautions should be observed in the carrying out of the procedure.

The bladder is never completely emptied with the catheter; hence, after the speculum has been introduced the residual fluid should be removed by a suction apparatus. The whole interior of the bladder can now be readily inspected by turning the speculum in the various directions. Applications directly to the diseased parts may now be made under the full aid of sight. Considerable pain is experienced by the patient in expelling the air which has rushed in to distend the bladder. To avert this, Kelly advises that the patient be carefully lowered and allowed to resume the horizontal posture with the cystoscope *in situ*, through which the air will again pass out. I have latterly availed myself of this suggestion, and have found that the patients suffer much less from tenesmus immediately following the examination.

In women bladder disturbances of greater or less severity are very common, so much so that it is seldom a woman will make complaint of micturition being too frequent unless the act occurs oftener than once an hour and is attended with pain and tenesmus.

The anatomical feature—the shortness and comparative straightness of the urethra in women—which makes them less prone than men to urethritis, accounts for their greater disposition to cystitis. The contiguity of the urethral opening to the vagina, and consequent infection from uterine and vaginal discharges; the exposure of the bladder and urethra to traumatism during labor; the frequency with which catheterism has to be done during the puerperium and after gynecological operations; the frequency of pelvic inflammations and displacements of the uterus which more or less involve the anatomical relations of the bladder; the periodic engorgement of the pelvic vessels, including those of the bladder, during menstruation, are all fruitful sources from which bladder disturbances may arise.

The most frequent condition met with is that which formerly was known as *irritable bladder*. Since the urine, as a rule, is normal in these cases, the term vesical pathology was assigned to the condition. At one time it would be looked upon as a mere manifestation of

hysteria, at another as an accompaniment of a fancied anteflexion of the uterus, at a third as a reflex symptom of uterine or rectal disease. Then, again, in another class of cases, some constitutional disease, especially malaria, was invoked as a causative factor. Kelly's method of direct inspection changed all this. It is now known positively that in the vast majority of cases the symptom is dependent upon a localized hyperemia of the bladder, usually involving what is known as the trigonum. The term *trigonitis*, not a happy selection, has been applied to the affection.

On cystoscopic examination the whole bladder surface may be found perfectly normal until the area bounded by the two ureteral orifices is brought within view. Here small irregular patches of a bright red color will be seen. They may involve the whole of the trigonal area, or be limited to the interureteral space. In these examinations one must bear in mind that the trigonum normally is more vascular than the remainder of the bladder. Hence one must not mistake the normal hyperemia of the part for disease, an error which can be guarded against with a little practice in healthy cases. The patches, as a rule, are well defined; occasionally they merge one into another, forming a single patch of larger size which covers the whole of the trigonal area. In another class of cases the red areas may be most marked immediately surrounding the ureteral orifices. When only one ureteral orifice is involved a suspicion of a tuberculous process in the corresponding kidney must be entertained—but of this later on.

Occasionally the vault of the bladder will present similar red patches. Kelly states that a little patch of hyperemia is always produced on the posterior vesical wall on withdrawing the obturator from the end of the speculum. This might be mistaken for a pathological condition. The error can be guarded against by noting its situation, which will be directly opposite the point of the cystoscope. On withdrawing the obturator it is always prudent, therefore, to inspect the bladder surface in the field of vision before changing the position of the instrument.

As already hinted at, the urine usually is perfectly normal.

This condition of localized hyperemia may be met with in association with the most varied pelvic affections; or, it may be seen, as it frequently is, independent of any other disease.

The Treatment.—Formerly the "irritable bladder" was the *hôte mûre* of the physician. It brought into reputation almost every drug in the pharmacopœia, and even a *dermocaust* of an artificial vesical fistula was made so that the urine could be entirely drawn away. Now, with Kelly's cystoscopic, reflex applications of a few centesims of cocaine to the ureteral orifices, and directly to the red patches, almost any case of *trigonitis* can be cured. I have yet to meet with a case that will not respond to this form of treatment. The next step, if the first fails, is to have treated

over fifty cases, and it was seldom the applications had to be made more than half a dozen times. In the majority of instances the symptoms were relieved permanently after the second or third application. For the twenty-four hours after the first treatment the symptoms were usually aggravated, but so marked is the relief subsequent to that that the patients invariably come back for treatment.

The ages of my patients varied from sixteen to sixty-five.

The following case illustrates how readily the treatment may be carried out in subjects the least promising:

The patient gives her age as fifty-six, but looks fully sixty-five. She is short, very corpulent, and is extremely nervous and awkward. For two years she has been suffering from painful and frequent micturition; she is obliged to get up four or five times during the night, and micturates every half hour or hour during the day. Various remedies have failed to give her any permanent relief. Lately the symptoms have been growing worse, making the patient very nervous and irritable. My office nurse experienced some difficulty in getting the fat old lady on the table in the proper knee-chest position. I made a rapid examination with a No. 10 cystoscope, without prior dilatation of the urethra, and found a number of red patches in the trigonal area. A solution of five-per-cent. of nitrate of silver was applied directly to the patches by means of a long, slender stick with absorbent cotton wrapped around its end. Four applications in all were made, at intervals of five and six days. The patient was then completely relieved from her former distressing symptoms, and has remained so now for five months. She was referred to me by Dr. J. W. Holfarth.

Next in frequency to irritable bladder, or, more correctly speaking, hyperæmia of the trigonum, comes catarrhal cystitis. In this affection our analysis of the urine usually affords us the means of forming a diagnosis. But not infrequently it is important to know whether the pus cells and blood-corpuscles found in the urine come from the bladder or from the kidney.

Microscopists tell us that they are always able to supply us with this information. The writer regrets to say that in his experience the information obtained from the microscopist has not always been reliable, and in several instances has been defective in clearing up the points in doubt.

The following case will serve to forcibly illustrate the unreliability of the microscopic examination, while showing at the same time the great therapeutic value of direct applications to the affected portions of the bladder in cystitis.

In the autumn of 1895 a patient suffering from an obscure vesical ailment was referred to me by Dr. C. W. Bohm. She was thirty-one years old, had been married ten years, and had never been pregnant. When she was twenty years of age she had pain across the lower dorsal region, and was supposed to have kidney disease, for which she was treated for several months. Had at that time oedema of the hands, feet, and face. The

hands and feet swell occasionally even now. A year after marriage she had a vaginal discharge which persisted for a long time. Four years ago she first began to suffer with painful and frequent micturition. These symptoms persisted with varying severity until the present time. At various periods she would have to keep to her bed for weeks at a time. For the six weeks prior to consulting me her bladder disturbances had grown very much worse. She had to keep to the house, for the most time remaining in bed. Lately blood in fairly large quantities was passed at the end of each urination. She had lost over ten pounds in weight and had become very nervous and hysterical. At first her bladder symptoms were supposed to be due to antelexion of the uterus. This organ, consequently, had been subjected to dilatation several times, and various kinds of antelexion pessaries tried. Then irrigations of the bladder had been employed, giving only temporary relief. She had gone the rounds of the specialists, all of whom tried something else with equally futile results. Finally, cystotomy was advised, and it was while the patient was trying to make up her mind to submit to this operation that she came under my care.

She was a tall, thin blonde, moderately anæmic, with a face wearing an expression of acute suffering. The kidneys were not palpable. The uterus lay in normal anteversion, was freely movable, and the cervix was irregularly torn on the right side. The annexa were apparently normal. The report of a pathologist of the microscopical examination of the urine was as follows: "Slight acid reaction; no albumin; large quantity of pus; a few red blood-corpuscles, a number of epithelia, suspicious of a growth. *Diagnosis* uncertain; may be papilloma of the bladder or pyelitis."

At this period (September 10, 1895) I was not yet very familiar with the use of the cystoscope. Hence the first examination was made under anaesthesia in the dorsal position. I was not certain whether I had seen the ureteral orifices. In the neighborhood of what I took to be the left ureteral orifice I saw a narrow streak about five millimetres long, from which blood was seen oozing. The whole of the trigonal area was intensely injected; the base and fundus of the bladder appeared normal, except that the vessels were unusually prominent and large. I was unable to catheterize the ureters from lack of experience, and, not being certain but that the blood seen oozing from the narrow line came from one of them, I sent a second specimen of urine to the pathologist with a report of my examination of the bladder. His second report was as follows: "Reaction slightly acid; large amount of albumin, due, however, to the presence of blood, from which the urine could not be separated. The microscope shows a large number of blood-corpuscles, but no pus cells; amorphous and granular matter, probably urates. Many epithelial cells of various kinds, very likely coming from the pelvis of the kidney." The probable diagnosis this time was a malignant growth in the kidney. From this time on (the first examination) I was enabled to examine the bladder without anaesthesia, the patient being in the knee-chest posture. I could now see distinctly that the blood came from the surface of the trigonum, and not from either ureteral orifices. I made a direct application of a five per-cent. solution of nitrate of silver to the whole of the affected area. At the next visit, five days later, the patient expressed herself as never having received so much relief from any form of treatment as she had from the preceding one. The

treatment was kept up for about six weeks (September 10th to October 29th), the applications varying in strength from a five-per-cent. to a ten-per-cent. solution of nitrate of silver, and made at intervals of from five to seven days. At the end of this time the patient could sleep the night through without urinating. During the day she could retain her urine for from four to six hours at a time. The bladder became perfectly normal in appearance, and the urine was free from any abnormal elements. The patient gained in weight, acquired a good color, and, from being a nervous, melancholic woman, became placid and cheerful. She has remained perfectly well ever since, and is one of my most grateful patients.

I have given the history of this case rather at length because it was very instructive to me, and because also it is typical of many cases I have treated since then, all with the same satisfactory results. The case emphasizes a feature of cystitis which is not generally known. It is commonly supposed that in cystitis the whole mucosa is equally affected. This is very seldom the case. As a rule, the disease is found in patches, with healthy mucosa between. At times there may be only one fair-sized patch; at other times there will be several small patches, usually distributed over the posterior wall of the bladder and over the trigonum.

Not infrequently small superficial ulcers, varying in size from that of a split pea to that of a ten-cent piece, will be seen in the affected area. After a little experience the eye is enabled to distinguish these from tubercular ulcerations. They appear more superficial, their surface is not so thickly coated, and no tubercle papules are seen in the vicinity.

It is not necessary for me to state that in these cases of catarrhal cystitis a suitable diet and regimen should be prescribed in addition to the local treatment. In the most severe cases, at the commencement of the treatment I frequently order suppositories of opium and a mixture containing benzoate of sodium and extract of hyoseyamus.

I have met with two cases which, for want of a better name, I must designate as *hamorrhagic cystitis*. They both were observed in pregnant women, the one in the third month of the ninth pregnancy, the second in the fifth month of the seventh pregnancy. The quantity of blood in the urine was out of proportion to the subjective and objective symptoms. In the one case there were a few red patches in the trigonal area, in the other the vessels at the base of the bladder were enlarged and tortuous. In both the blood rapidly disappeared from the urine after a few direct applications of a five per cent. solution of nitrate of silver.

One of the patients has recently returned, after the lapse of a year, suffering anew from frequent and painful micturition. These symptoms set in about six weeks ago. There has been no further hamaturia, but the local signs are suspicious of tuberclosis.

We now come to a class of cases which, though com-

paratively rare, are more often met with at the present time, when our means of diagnosis have been improved by the method of direct inspection. I refer to tuberculous disease of the bladder as a primary affection. Dr. Edward Reynolds* has reported four cases. Dr. J. O. Polak† described one case, and recent literature contains several other cases.

I myself have met with two cases during the past three years. One case passed from under observation after a short time; the second is still under treatment and is worthy of a brief description, as it demonstrates what local treatment may do even in these cases.

Mrs. S. came under my care December 14, 1897. She was forty-seven years old, had been married twenty-nine years, had eleven children and one miscarriage. Last child was thirteen years old. There is no tuberculous history in the family. Her menses were still regular and normal. For six years she had been suffering from frequent and painful micturition. Latterly the symptoms were growing more severe and were worse during the night, when she would be compelled to get up every ten or fifteen minutes. During the day she could hold her urine for half an hour, or sometimes for an hour. The act of micturition was attended with considerable pain and tenesmus. So far as she knew, she had never passed blood with her urine.

On cystoscopic examination the trigonum was normal in appearance, as were also both ureteral orifices, which were seen to emit jets of clear urine. On the posterior wall of the bladder, a little to the left of the median line, and some distance from the trigonum, was an elongated patch of intense redness. The patch looked at first like a streak of bright blood, but it could not be wiped away. The vessels immediately surrounding the patch were intensely infected. The right half of the vesical mucosa appeared normal. At a subsequent examination, a short time later, six small, pale papules about the size of a pin's head were seen distributed about the trigonal extremity of the patch. A diagnosis of tuberculous cystitis was made. A specimen of urine with some of the scrapings from the surface of the affected area were then sent to Dr. Harns-worth, House Physician of the Mount Sinai Hospital, who kindly made a bacteriological examination and found a few tubercle bacilli.

Weekly applications were made of nitrate of silver, beginning with a five per cent. solution and increasing up to a forty-per cent. After a half dozen applications the symptoms markedly improved, and I did the local signs. The patient did not have to get up during the night oftener than once in four or five hours, and the day she could easily hold her urine for two or three hours. The pain attending the act of urination had almost entirely disappeared. There has been no further passage of blood in the urine, and no micturition; she still has to get up several times during the night, and cannot retain her urine for a longer period than four hours during the day. With a few interruptions, the treatment was continued for a total of twelve weeks. I have not varied the mode of treatment, but have increased the concentration of the solution from five to fifty per cent. and have used the nitrate of silver with good results. I am confident that the patient will

* American Medical Association, 1895, p. 13.

† American Medical Association, 1895, p. 13.

glycerin for a long period. The application was painless, but I did not observe much improvement in the local condition under its use. The best results seemed to be derived from strong solutions of nitrate of silver and from a twenty-five-per-cent. solution of ichthyol in glycerin. At the present time the red patch has about entirely disappeared, but fresh tubercles appear in the vicinity from time to time. At no period during my observation of her has ulceration in the affected area taken place.

The situation of the tuberculous process will explain why it was that the patient suffered more while in bed than when up and about. In the recumbent posture, as soon as a small quantity of urine collected in the bladder, it would reach the affected area and excite a desire to urinate. In the erect posture, on the other hand, the urine could collect at the base of the bladder for some time before it would reach as high as the diseased part.

When evidences of tuberculosis are observed in the bladder the greatest care should be taken to exclude renal tuberculosis, for in the majority of cases the bladder becomes secondarily infected from a lesion in the kidney. The opposite holds good also—cases in which the tuberculosis primarily develops in the bladder and ascends to one or other kidneys or to both. In the first class of cases the tract of infection may frequently be traced. The mouth of the ureter of the affected kidney will be swollen and very much reddened, and if there be further involvement of the bladder it will at first be seen in the neighborhood of the ureteral orifice. A marked injection about the ureteral meatus, with the remainder of the vesical mucosa perfectly healthy, is very suspicious of tuberculosis of the kidney of that side. L. Casper* and Willy Meyer† have each diagnosed an early tuberculosis of the kidney from this local sign, and the diagnosis in both instances was substantiated by a subsequent nephrectomy.

The writer‡ has reported a case of nephrectomy for early tuberculosis of the kidney in which the diagnosis was made by finding a stricture of the ureter about an inch from the bladder.

In the above-reported case of vesical tuberculosis fresh papules, few in number, appear from time to time. Each new crop seems to be advancing nearer toward the left ureteral orifice. The writer is watching the case with the most intense interest, and if later developments bring forth any fresh points of interest he will publish them in a future communication.

SARCOMA OF THE NASAL SÆPTUM.*

BY J. PAYSON CLARK, M. D.

THE number of reported cases of sarcoma of the nasal passages is still sufficiently small to rank this among the less common nasal affections and to make of value complete reports of all observed cases. Bosworth, in 1889, had collected forty-one cases, about half of which were sarcoma of the septum. In a paper on sarcoma of the nose in 1891 I added seven cases to this list, and Boylan, in 1896, added fourteen more. Since 1896 I have found references to fourteen cases, but have been able to consult the reports of only ten. Boylan says of the twenty-one cases which he collected (seven of which were mentioned by me in 1891) that in two cases no operation was attempted, in two it was admittedly incomplete, leaving seventeen in which extirpation was attempted. Of these, two are recorded to have died of recurrence, and in five no subsequent history is referred to. In seven, the length of time the case was observed after operation is not given. In only three is it distinctly stated that there was no recurrence a year or more after the operation. In Boylan's case the growth, a spindle-celled sarcoma, was removed by means of a snare, and the site on the lower turbinate thoroughly curetted. There was no sign of recurrence over a year after the operation. In the ten cases since 1896, the records of which I have been able to consult, seven died of the disease, and one (Bliss's second patient), although living at the time of the report, was in such poor condition and presented such an extensive growth that operation was thought inadvisable, while another (Nichols's Case III), in which the growth was also very extensive, was lost sight of. The one which recovered (G. M. Black's) was a woman of thirty-eight with an alveolar sarcoma of the right middle turbinate, which was removed by means of the snare and curette. There had been no recurrence over two years later. In one of the seven fatal cases no operation was attempted. This case (Scheppegrell's) was in a man, fifty-six years of age, with a round-celled sarcoma of the quadrangular cartilage. The growth was so extensive that operation was not considered justifiable. In another fatal case (Bliss's), that of a boy, aged four years, the growth was so extensive that only a palliative operation was attempted. Following are brief reports of the five remaining cases:

Bonain: A boy of thirteen years had a polyp of left inferior turbinate removed by snare and pedicle destroyed by galvano-cantery. The polyp (there is no record of its microscopic character) recurred in the course of a year and was treated in the same manner. Six months later the left nostril was occluded by a soft, dark-red tumor from the lower turbinate. This was thoroughly removed, but recurred in four weeks. Further operation was refused, the growth increased rap-

* Read before the American Laryngological Association at its twenty-sixth annual congress.

idly, and the patient died a year and ten months after being first seen. The growth was a myxo-angio-sarcoma.

Onodi: A man, aged fifty, had both nostrils filled with apparently benign polypi, which were treated with snare and cautery. The left nostril remained free, but the right refilled in several months. Some of the recurrent growths did not differ in appearance from rather dense polypi, while those on the middle turbinate had a suspicious appearance and were found on microscopic examination to be round-celled sarcomata. All growths were removed and suspicious-looking places cauterized. Ten months later there was no sign of recurrence, but eleven months after this the right nostril was again filled with the growth. A radical operation was advised and performed (two years and a half after the patient was first seen for polypi). The patient died two months later from a rapid recurrence.

Greene: A woman, aged thirty-two, had nasal stenosis, with pain and frequent epistaxis. A growth discovered between the middle and lower turbinates on the right was removed with forceps. Three months later the growth had extended to the orbit and ethmoid. No radical operation was attempted, and the patient died five months after she was first seen. The tumor proved to be a mixed sarcoma and carcinoma.

Nichols: 1. A woman, aged twenty-seven, had a polyp (?) removed from the left nostril one year before. When first seen by Nichols the growth was very extensive, involving left antrum and sphenoidal cells. An extensive operation was done, and later antitoxine treatment was tried without avail, the patient dying three months after the operation. 2. A girl, aged seventeen, had obstruction of left nostril for several months. A dense tumor (myxosarcoma) filled left nostril. It extended into the antrum and ethmoid cells. It was removed by snare and sharp spoon and ethmoid cells curetted. For six months the patient was well, then the growth recurred in the sphenoidal region. The tumor was removed as thoroughly as possible, and the patient remained in good condition for a year. Then the growth recurred, increased with great rapidity, and resulted in death a little less than two years after the first operation.

The case which I have to report is one of sarcoma of the nasal septum. I shall take this occasion to give also the subsequent history of a similar case which I reported in the *Boston Medical and Surgical Journal*, September 3, 1891. A brief résumé of the history of this case as then given is as follows:

G. W., aged thirty-five, was first seen by me in July, 1890. He first noticed obstruction of the left nostril three months before. This nostril was found to be filled with a bluish-gray mass. This was removed in several sittings by means of a cold-wire snare. One month after this operation (September 29th) the mucous membrane appeared everywhere normal. There was nothing to show where the tumor had been attached. But a month later a small, rounded elevation was seen on the septum near the posterior border, and two weeks after a growth of the size of a large bean was removed from this site. The patient was kept under observation during the winter. The growth showed little tendency to increase, although it never disappeared entirely. On May 2, 1891, a recurrence the same size as the last was removed. From this time the growth began to be more rapid, but

it was not until January, 1892, that I concluded that the snare and curette were inadequate for its thorough removal. Then, at my request, Dr. J. C. Warren removed the whole septum under ether, having first laid the nose over on to one cheek (Brun's operation), in order to get at the septum better. Dr. W. F. Whitney reported: "Septum thickened by a spicula-looking formation of bone, on the outside of which was a soft, grayish, more or less translucent new growth—osteoid sarcoma." The whole septum showed this appearance. Dr. Warren went as high up in the nose as possible, but the disease went farther. The course of the disease from this time on was very rapid. The growth soon involved the left orbit, destroying vision in that eye. It also appeared in the scar of the operation in a cauliflower mass. The patient suffered from severe headaches and occasional severe hemorrhages from the nose. He became dull and stupid, and when last seen, in June, 1892, it was evident that he had not long to live.

Mrs. W. H. M., aged forty-two, was first seen by me June 1, 1897, when she gave the following history: Her father had a cancer of the lip removed eight years ago and is now living, aged seventy-five. Her only sister died three years ago of cancer of the liver. Her maternal grandfather died in old age of cancer of the stomach. The patient has always been well. Has eight children living. Lost one in infancy. About two years ago she noticed that the left nostril was obstructed, and soon perceived a "lump" in the nostril, which bled easily. There was a disagreeable nasal discharge. Examination showed a dark, reddish-gray tumor filling the anterior portion of the left nostril, also visible by posterior rhinoscopy. This growth was removed in several pieces by the cold-wire snare. It was very friable, but did not bleed profusely. After the growth had been thoroughly removed, it was seen to have been attached to the cartilaginous septum by a pedicle about a centimetre in diameter, nearly opposite the lower border of the middle turbinate. At the site of the attachment of the growth was an area of cartilage denuded of mucous membrane, not quite a centimetre in diameter. Dr. J. H. Wright, the resident pathologist of the Massachusetts General Hospital, gave the following report: "The growth consists for the most part of small cells with long branching processes forming a loose reticulum, in which a mucinlike material is present, as shown by a bluish staining with hematoxylin. In places this tissue merges into a hyaline semi-fibrillar substance, which seems to represent degenerate tissue. There are also areas made up of small, oval, nucleated cells closely packed together. A few thin-walled, atypical blood vessels are present. Diagnosis: Myxosarcoma." As the patient lived at a great distance, and could not therefore be under observation, it seemed best to remove the site of the growth, together with considerable surrounding tissue. This operation was done by Dr. S. J. Mixer on June 19th. A triangular incision was made over the bridge of the nose, the cartilage sawed through with a fine saw, and the nose turned down over the mouth. Most of the cartilage, and part of the bony septum was removed with the osteoid forceps. The nose was replaced and the patient made a good recovery. The portion of the site of removal showed no evidence of sarcomatous growth. The report was seen again on September 29th. Several months and slight epistaxis. Examination revealed no evidence of recurrence. A small polypoid mass of mucous membrane at the junction of the nostril with the alar wall, with the

floor of the nose was removed and examined microscopically. It was "hypertrophied mucous tissue." A letter from the patient's doctor dated March 28, 1898, says that there is at the junction of the septum remains with the floor of the septum a little enlargement, but this has not changed in size or appearance. This is undoubtedly the same "hypertrophied mucous tissue" mentioned above. Otherwise the septum looked well.

On the aetiology of nasal sarcoma the cases which I have here collected throw no new light. It would seem at first as if three of these cases lent support to the theory that myxoma may become converted into sarcoma. However, in Bonain's case there was no microscopical examination of the so-called polyp, which besides grew from the lower turbinate, a very unusual site for polypi. There was no microscopic examination of the polyp in Nichols's case, besides which the whole history in this case seems to indicate that the growth was malignant from the first, while in Onodi's case there is nothing to show an aetiological connection between the polyp and the sarcoma. They seem rather to have originated independently. It seems to me, after a study of the literature, that we are no longer justified in assuming that sarcoma in the nasal passages is less malignant than in other localities. It is less malignant only in so far as it may be in a situation to be thoroughly eradicated. The case of G. W. indicates well the extreme malignancy of the round-celled variety; and while Bosworth's statement, that the intermingling of normal tissue elements renders the prognosis less grave as the proportion of normal elements increases in the tumor, is undoubtedly true, still we should not be led into giving a favorable prognosis in any case because we find a mixed growth. That such a mixed growth may be extremely malignant, Bonain's and one of Nichols's cases (myxosarcoma) show. As regards treatment, I think no one will deny, in the light of the subsequent history, that the only chance for the eradication of the sarcoma in the case of G. W. would have been the removal of the whole bony septum when the patient was first seen. The slow growth of such a neoplasm should never deceive us as to its real malignancy, or lead us to adopt any half-measures in treatment, because the history of many cases shows that an apparently quiescent sarcoma may suddenly and without any warning take on a terribly rapid growth. Given a round-celled sarcoma on a structure like the nasal septum or one of the turbinates, it should be removed at once, together with a wide margin of normal tissue. If the sarcomatous elements are mingled with normal tissue elements, as in fibrosarcoma, myxosarcoma, etc., one may be justified in attempting their removal by means of the snare and curette, provided the patient can be seen often and the part closely watched for any recurrence. But in case the patient lives at a distance, or for any other reason can not be under the watchful care of the physician at frequent intervals for one to two years, a radical operation should be performed at once in the case of a round-celled sarcoma. The condition

of the septum in the case of Mrs. M. showed that a snare and curette would have probably entirely removed the growth, but under the circumstances I did not feel justified in taking the risk.

The performance of such an operation does not dispense with the subsequent close watching of the nasal cavity, when that is possible. In case of recurrence after an operation with snare and curette no further attempt should be made to operate in this manner, but a radical operation should be at once resorted to. In view of the horrible condition of the patient who dies of this disease, it certainly seems far preferable to perhaps remove too much normal tissue at first than to suddenly discover that the disease has extended beyond the reach of the surgeon's knife.

THE TREATMENT OF PNEUMONIA.

By SIMON BARUCH, M. D.

AN essay on the State of the Vasomotors in Lobar Pneumonia, and its bearing upon Treatment, which appeared in the *New York Medical Journal* for October 8, 1893, presents the important subject of treatment in an interesting light, because it differs widely from the usual crude or empirical views found in our literature.

The paramount import of the vasomotors is clearly set forth by the author, and an attempt is made to deduce a correct treatment from the ascertained conditions, viz., the relaxation of the peripheral vessels. The able author refers to Romberg's and Passler's experiments with injections of pneumococci into the circulation of

rabbits, which demonstrate the import of vasomotor involvement. This is of special interest to me, because he confirms my clinical observations of the past ten years, which were offered to the New York Academy of Medicine not long ago.* In this essay the following statement was made: "Romberg has recently confirmed what I have several years ago and repeatedly since that time insisted upon, that in acute infectious diseases we encounter disturbances of the circulation which manifest themselves clinically as reduced tension and diminished filling of the arteries, and which are commonly described as heart failure. Undoubtedly the condition of the peripheral vessels bears a very large share in the production of cardiac inadequacy, as I have sought to impress when explaining the *rationale* of cold applications in typhoid fever and pneumonia. Romberg has shown by experiments with injections into rabbits of Fraenkel's diplococci that the circulation is damaged by a paralysis of the vasomotor, while the heart itself remains unaffected." That the same condition of the peripheral vessels exists in lobar pneumonia is demonstrated by the clinical observations of Van Santvoord, who found that "chloride of barium in doses of four grains every four hours produced in one case a material contraction of the very much relaxed arteries, the pulse slowed, and the marked delirium and prostration of the patient disappeared, although the temperature and pulmonary lesion remained unchanged. In other cases no material result followed the same treatment." The fact that "strychnine, which is now so widely used, not only has a tonic effect upon the heart, but also causes contraction of the peripheral vessels, through its action upon the spinal vasomotor centres, which, according to Romberg, are not affected by the pneumococcus," is also cited in support of the theory that a relaxation of the peripheral vessels in pneumonia exists. The author states that "the most obvious method of combating extreme dilatation of the peripheral vessels" (to which he justly attributes cardiac failure) "is to administer drugs which cause their contraction." Inasmuch as he clearly states that in only one case out of several the drug, "which has been proved to act on the peripheral vasomotors," really produced any improvement, there seems to be little hope of discovering a more efficient one.

Shall we confine our search for such remedial agents to drugs whose action at best is either unreliable or connected with some undesirable effect? Clinical observation has already demonstrated conclusively that we may find outside of pharmacy a most potent agent for this purpose in cold applications to the cutaneous surface, which presents an enormous "peripheral circulation." My advocacy of this therapeutic agent is, however, not based upon clinical experience alone. I agree with Horatio Wood that "therapeutics developed by empiricism or clinical experience alone can not rest upon a

secure foundation. Experiments upon the lower animals or upon healthy human beings are the only rational scientific groundwork for the treatment of disease." Roehrig has shown by experiments on frogs that feeble cutaneous irritants enhance the normal tone of the circular muscular fibres of the vessels, and that intense irritants permit a relaxation of these muscular fibres. This has been confirmed by Naumann and others. These observers have shown that *weak* cutaneous irritants produce a narrowing of the small arterioles, with a rise of pressure, in consequence of which the resistance at the periphery is enhanced, and thus the heart is made to contract more rapidly. *Intense* cutaneous irritants, on the other hand, fatigue and paralyze the normally existing innervation of the blood-vessels, which emanates from the medulla oblongata, and therefore produce a relaxation and dilatation of the peripheral arterioles, with diminution of pressure. That the toxic agents circulating in the blood in certain infectious diseases belong to the latter class has been demonstrated by Romberg and Paessler. That the application of cold water to the cutaneous surface belongs to the former class (feeble cutaneous irritants) has been demonstrated by Winternitz.

From these demonstrated facts a rational treatment of pneumonia has been deduced, to which the attention of the medical profession needs to be directed.

The application of cold water to the skin produces, like other mild cutaneous irritants, a narrowing of the cutaneous vessels, which, followed by their tonic dilatation during reaction, causes the blood pressure to rise and improves cardiac action. The sphygmograph demonstrates that this dilatation of the peripheral vessels, following their narrowing in reaction, is not accompanied by loss of tone and is not passive, as is illustrated by the following tracings:

No. 1 represents the pulse of a man who had been smoking excessively. It shows a pulse of low tension, considerable diastolism, small tidal wave, evidencing feeble ventricular action, indicated by a slanting and low up-stroke, and a somewhat obtuse per-recession wave. The pulse was 90, respiration 18, and temperature 99.4° F.

This man was subjected to a full bath at 80° F. for twelve minutes, with the result of completely changing the character of his pulse. The tension is shown by the subjoined tracing, taken after the bath, to be decidedly improved; it shows a marked tidal wave, very moderate

diastolism, a quick vertical up-stroke, and a per-recession wave. The pulse was reduced to 72, the temperature to normal, and the respiration now increased to 21.

* The Management of Pneumonia Patients. *Medical News*, January 9, 1897.

I have for many years expressed the belief that this tonic effect upon the heart is due to the fact that the peripheral vessels possess the power of propelling the blood through these fine tubes, and thus bear a larger share in the circulation than is commonly suspected. This effect I have long claimed is enhanced by the application of cold water to the skin, which produces first a contraction and subsequently a tonic dilatation, with increased contractility of the walls of the fine peripheral vessels, relieving the heart enormously, and freeing it from the added labor which threatens to exhaust it in infectious diseases, in which there is a loss of this propulsive power, due to passive relaxation of the peripheral vessel walls, by which normal resistance is removed. Professor Hobart A. Hare demonstrates his great aptness as a teacher by the ingenious comparison of the heart to a locomotive.* He says, correctly, that the vasomotor system is made up, on the one hand, by the vasomotor nervous apparatus, and, on the other, by the blood-vessels themselves. The resistance offered to the heart by the properly acting vasomotor nervous system, through its influence on the vessels, is identical with the friction offered to the driving wheels of a locomotive. The locomotive is intended to meet and stand any resistance, but when the latter is removed by slippery rails the wheels fly around ineffectually, racking the machinery and destroying its usefulness. He maintains justly that "a rapid pulse may be due in no way to a disordered heart, but to vasomotor relaxation, and that the proper treatment is to put sand on the track to increase the resistance, and not to make more steam—or give digitalis—which will only cause the engine or heart to work away on slippery rails, with more wear and tear and no progress." *The cold bath increases the resistance.*†

That the explanation of the action of cold hydropathic procedure in infectious diseases which I have given is correct, has recently been confirmed by Dr. Woods Hutchinson,‡ professor of comparative physiology in the University of Buffalo, who argues ingeniously from comparative anatomy the existence of elasticity in the peripheral vessels, which aids in propelling the blood onward, and states that the calibre of the arteries and arterioles, particularly the latter, varies very considerably from time to time, so as markedly to influence the flow of blood to the part supplied by them, and that these changes of calibre are brought about by the vital contraction or relaxation of the firm and powerful muscular wall, which extends from the largest arteries down to the mouths of the very capillaries themselves.

Hutchinson concludes: 1. That the existence of active contractility upon the part of the muscular wall

of the arteries and arterioles, and in less degree of the veins and lymphatics, and of the capillary epithelium, is something which we have the strongest reason to expect upon ancestral ground in even the highest animals.

2. That the beneficial effects of cold water upon the circulation, accompanied by friction, as in the Brand method of typhoid fever, are adequately to be explained only upon the ground of the persistence of such a power in our mammalian "skin heart."

3. The occurrence of this sort of contraction is almost universal in invertebrates (having been seen even in the higher vertebrates—the wing of the bat, and the ear of the rabbit), so that we have abundant ground for the possibility and some even for the probability of its occurrence in our own species.

Thus theory, experiment, and logical reasoning have confirmed the clinical observation of those who resort to cold hydropathic procedure in infectious diseases. Even if the temperature is not materially reduced by them, the pulse almost always demonstrates improved heart action. The application of these principles to the therapy of pneumonia has been of great interest to me. Careful observation at the bedside during the past ten years has brought me to the abandonment of the cold, full bath, chiefly because it is too disturbing to the patient, and the latter does not require it, because there is not usually a serious involvement of the nervous system, and also because the body cools very rapidly in this disease after any decided cold procedure. I have therefore substituted a more mild procedure—the wet chest compress. The latter consists of several layers of old linen cloth, wrung more or less out of water at 60° or more, and repeated every half to two hours, according to the patient's condition and temperature, applied snugly around the entire chest, and covered with flannel. This has in my hands proved quite sufficient to produce all the effects of cold water. The first effect of such a compress is a shock to the peripheral nerves, followed rapidly by a reaction which is conveyed to the central nervous system, and thence reflected to the lungs, causing deeper inspiration and increased expectoration; to the heart rendering the pulse slower, more tense, and resisting. When the compress becomes heated by contact with the hot skin, evaporation through the flannel covering ensues, causing heat diffusion and consequent local cooling. Removal of the compress produces a repetition of the shock and reaction, with the same effect upon the respiratory and vasomotor centres.

No drug is capable of accomplishing the same result. I am not averse to the use of drugs, and often resort to hypodermics of strychnine to tide over temporary cardiac inadequacy, but I depend almost entirely on the cold compresses to meet the most pressing indications of improving the circulation and respiration, increasing renal elimination and reducing temperature. Since alcoholic stimulants produce in large doses the same conditions of the cutaneous vessels as the injection of the

* *Therapeutic Gazette*, vol. xii, No. 2.

‡ *The Skin Heart*, *Boston Medical and Surgical Journal*, November, 1897.

pneumococcus produces, I do not resort to them, except in alcoholics to whom they have become a daily necessity.

The lessons of Dr. Van Santvoord's admirable essay are that drugs are demanded to counteract the dangerous relaxation of the peripheral vessels, and that drugs have thus far failed to accomplish this desirable result. The lesson I desire to emphasize is that the cold, wet compress, judiciously adapted to each individual case of pneumonia, not only restores the tone of the relaxed peripheral vessels, but possesses other therapeutic qualities which render it the most useful agent in the treatment of this disease.

SPASMODIC CLOSURE OF THE GLOTTIS IN THE ADULT.

A CASE.

By HAMILTON STILLSON, M.D.,
SEATTLE, WASHINGTON.

For the meeting of the American Medical Association of 1897, at Philadelphia, I furnished an article on Spasmodic Closure of the Glottis in the Adult, closing the article with the report of a case. While that case had hypertrophies of the turbinates and septal spurs, the spasm of the glottis did not seem to be caused by the nasal complications, but by tabes dorsalis of rheumatic origin. I have recently had another case of this rare but very disagreeable affection that seemed to have been caused by nasal complications alone; and, though the disease is rare, its importance justifies a complete report of every new case. I therefore submit the following:

On June 26, 1897, E. B. N., a printer, about thirty years of age, apparently in robust health, consulted me, complaining that every night he would find himself suddenly out of bed and in the middle of the floor gasping for breath; attempts at inhalation very noisy, very difficult, and very distressing; could not state the length of time occupied by these spasms—"it seemed several minutes." Stated that he could not get his breath until unconsciousness had almost supervened. These attacks never occurred in the daytime, and never occurred at night during wakefulness.

Under good illumination I elicited an exhibition of the spasm by touching the vocal cords with a probe. The cords fell together like a valve, and efforts at inhalation seemed to suck them closer together. A short view only was obtained of them in this condition, the patient leaning forward over the cuspidor and allowing tenacious saliva to run from the mouth; then, without premonitory coughing, he made violent attempts at inhalation. A short gurgling whoop was heard, and was repeated about every second for about ten seconds. Between the whoops there was a period of exhalation, short and easy. After the first or second attempt at inhalation the patient stood up, paced the floor uneasily, his arms partially extended by his sides, his chin high in the air, and his head thrown back. Profound cyanosis was rap-

idly supervened; the ocular conjunctiva became quickly congested, the eyeballs rolling upward in profuse lachrymation. After about ten seconds the violence of the spasm had passed, though the patient seemed ready to collapse. His distress caused me to administer chloroform, whereupon the inhalations became deeper and less noisy, and were made without so much effort. The inhalations were for several seconds longer, irregular, and wavy. The voice in attempts at phonation also was quavering. The entire attack lasted about thirty seconds. For a moment or two longer the pulse was a little irregular and slightly accelerated. The surface of the body, particularly that of the extremities, was cold to the touch and livid under pressure. The patient did not express any particular discomfort after the attack had passed. There were no evidences of rheumatism, or syphilis, or tuberculosis. The patient did not use alcoholic beverages or tobacco. His general health in other respects was, so far as could be determined, very good. Examination of his nose and throat revealed a large septal spur on the left side of the septum, and deviation toward the left. There was hypertrophy of the lower and middle turbinates, right and left, polypoidal degeneration of the mucous membrane posteriorly, hypertrophy of the lingual tonsil, and hyperemia of the epiglottis and false cords.

Under cocaine anæsthesia I removed the hypertrophy of the left lower turbinate. On June 30th I removed the septal spur with a Bosworth saw. On July 2d he reported the spasms of the larynx less severe, though not less frequent. On July 5th he reported that Saturday night, July 3d, was the first night of good sleep he had had for weeks. There was no laryngeal spasm, and the patient was unduly elated and celebrated the 4th in the most approved style. On the night of the 14th the "nose swelled up again," and he had one of the most severe attacks. I relieved the congested condition with cocaine, and dressed the nose with a bland astringent dressing, which I continued to use until July 20th, when the cut surface had healed. The spasms were now intermittent and not severe. On July 20th I removed the hypertrophy of the right lower turbinate, applying acetate of aluminum as a dressing. The spasms at once ceased, and the cut healed kindly. On July 21st I dismissed the man with both nostrils patent, and no spasm being elicited by touching the mucous membranes with a probe. The patient left for Alaska, attempting to go to the Klondike over the Skagway trail. He worked in "mud and slush" until almost exhausted, and when opportunity offered he lay down and "slept like a baby." Not being able by his utmost exertions to get his equipment across the trail, he returned to Seattle on August 14th for a new supply of horses. He called to see me and report that he had had no symptoms of cough or strangulation. He returned to Skagway with his horses, and made the trip across the trail to Dawson City, where he remained until about the 1st of October, 1898, when he returned, looking quite well, and reporting that the only indication of a relapse of the spasm was the presence of a slight tickling in the throat, which he experienced one night at Dawson City. I consider him permanently cured.

These two cases are in line with Bosworth's belief that attacks of spasmodic closure of the glottis in the adult occurring in the daytime, especially when exhibiting permanent paresis, or paralysis, of one or more of the laryngeal abductor muscles, indicate a central nerve les-

sion; while such attacks occurring at night, and not manifesting permanent impairment of motility in the abductors, may be judged purely "reflex" in character.

THYREOTOMY IN PAPILLOMA OF THE LARYNX IN ADULTS.*

By T. MELVILLE HARDIE, M. D.,
CHICAGO.

It is too short a time since the publication of Heymann's *Handbuch der Laryngologie* to make a historical or a bibliographical review of the operation of thyreotomy either necessary or interesting, and I shall, therefore, limit this paper to a report of two cases of laryngeal papilloma in adults on whom I performed thyreotomy, and to the incidental statement of the indications for the operation:

CASE I.—John B., aged nineteen, was referred to me June 27, 1894, on account of such difficulty in breathing as compelled him to give up work. Inquiry as to family and personal history elicited nothing of particular importance. The patient's lips were bluish and he had a slight stridor, which was increased upon exertion. He had lost in weight, was hoarse, suffered no pain; the mucous membrane of the mouth and pharynx was anæmic. Inspection of the larynx showed the cause of the dyspnoea to be a pale subglottic tumor, involving the anterior commissure and apparently attached to both vocal cords, on their under surfaces, and to the anterior wall of the lower larynx. The extent of the growth inferiorly could not be determined. Iodide of potassium had no effect.

On three occasions it was found possible to remove portions of the growth with a Juaraz laryngeal forceps, but with no effective relief to the breathing. On microscopical examination the fragment was pronounced papilloma. As I hoped to be able to remove much of the growth by endolaryngeal procedures, I did a high tracheotomy under cocaine anaesthesia and inserted a tube, which completely disposed of the dyspnoea. Endolaryngeal operations with snare, curette, forceps, and galvano-cautery were resumed with but slight benefit, and since then consumed a great deal of time, and the patient complained further that no one would employ him on account of his tracheotomy tube, a thyreotomy was decided upon.

A Hahn's tampon cannula was inserted into the original tracheotomy opening, which I enlarged a little, and after a few minutes the thyroid was split and the cartilages held apart with retractors. It was noticed at this instant that the patient was not breathing, the evident cause for the accident being a bend in the chloroform tube, which was caused by the anesthetist, who was stationed at the foot of the table, becoming interested in the operation. I detached the anæsthetic tube from the tracheal cannula; we raised the foot of the table so that the patient was hanging head downward, and performed artificial respiration. On the patient's breathing again I completed the excision of the

growth with scissors, and cauterized its wide place of attachment. Bleeding almost immediately ceased, and I sutured both the thyroid plates and the external incision. The tampon cannula was removed and an ordinary double-tube silver tracheotomy tube was introduced.

The patient's recovery was uninterrupted, but I foolishly made him wear the tracheotomy tube for nearly two months. This was done some years ago, and I did not know any better. I persuaded myself that I was right, because I wished to be prepared for a possible recurrence, and so that I might see the patient for some time subsequent to the operation. I saw the patient a little more than one year after the operation. There had been no return of the growth; his voice was slightly hoarse, but good, and the somewhat prolonged sojourn of the tracheotomy tube had done no visible harm.

CASE II.—Julie K., aged forty-nine, married, appeared at my clinic at the Post-graduate School, March, 1895. On account of her aphonia she required an interpreter, who informed me that the patient, her mother, had been hoarse and had difficulty in breathing for a long time before she lost her voice. In January, 1895, the breathing became so bad that a surgeon performed tracheotomy, which relieved her at once; but the spasmodic cough from which her mother suffered caused them great concern, and they wondered, further, whether nothing could be done to recover the voice. The woman was emaciated and feeble.

Examination of the lungs demonstrated an extensive bronchitis, with little, but very tenacious, secretion. The patient made vigorous attempts at making herself understood, but could only move her lips and make such sounds as I could not describe without the assistance of a phonograph. It was evident that no air was inspired through the mouth or nose. On using the mirror I saw a papilloma, which completely filled the upper larynx, and covered its posterior wall so that only the epiglottis was to be seen. Touching the tumor with a probe excited so severe and so prolonged a spasm of coughing that I had to wait ten minutes before spraying the tumor with a ten-per-cent. solution of cocaine.

This proceeding again excited severe cough, and all attempts at securing even partial anaesthesia by means of the cocaine with spray and absorbent cotton brush were unavailing. The spasms were so severe, both at the first and at succeeding examinations, that every attempt to encircle the growth by means of a wire snare, or to grasp it with forceps, was unsuccessful. Bromides were given, and cocaine was used in as large amount as was considered safe.

I regretfully concluded that I could not remove the growth through the mouth, and therefore, on March 29, 1895, split the larynx under chloroform anaesthesia. I had secured the smallest Hahn cannula to be had in Chicago, but found, when I enlarged the original tracheal opening, that it was impossible to introduce it into the very small trachea which presented. The original tracheotomy had been a very high one, and I therefore made the incision from just above the thyroid notch to the tracheotomy opening. Before opening the larynx I had the head lowered so that the blood could not run down the trachea, and then cut through the cricoid and thyroid cartilages as nearly as possible in the middle line.

* Read before the American Laryngological Association at its twenty-fifth annual congress.

On separating the cartilages it was seen that the papilloma was attached by a comparatively small base near the anterior end of the left vocal cord. It was removed by means of an ordinary nasal snare and its base cauterized with chromic acid. A little iodoform powder was dusted in the larynx and externally. The cartilages were not sutured, but carefully approximated, and the skin was sewed with silk. The tracheotomy tube was left in for three weeks.

The voice was hoarse, but improved gradually. There were very few attacks of the spasmodic coughing after the operation, and the bronchitis was entirely recovered from with great benefit to the patient's general condition. Two or three granulations at the anterior commissure required endolaryngeal cauterization, but there was no recurrence of the papilloma while the patient was under observation, a period of six months only. I omitted the sutures so far as the cartilages were concerned, in order to compare the result with that in my first case.

A CASE OF EXTERNAL CARBOLIC-ACID POISONING TREATED WITH SODIUM-SULPHATE SOLUTION.

RAPID RECOVERY.

By BERNARD WEISS, M.D.,

ASSISTANT ATTENDING PHYSICIAN, BELLEVUE HOSPITAL,
OUT-PATIENT DEPARTMENT.

Mrs. S. B. was advised by her physician to use vaginal douches with carbolic acid for a discharge after a miscarriage. One evening a fountain syringe was filled with warm water and then "just a little" of pure (ninety-five per cent.) carbolic acid was poured in from a bottle. With this mixture the patient syringed herself and allowed the outflowing water to run into a bedpan which had been placed beneath her. As soon as the syringing was begun extreme burning was felt inside; nevertheless, the entire fountain-bag was allowed to empty itself. In a few minutes the patient felt agonizing pain all over her pelvis and began to shriek from suffering. On my arrival the tissues were found to be very tender to the touch and large eschars appeared wherever the solution had touched the skin, whether inside or outside.

The patient was immediately syringed with a warm solution of sodium sulphate, one drachm to the pint, and cloths saturated with the same solution placed on her blistered thighs, etc. Within ten minutes the patient felt somewhat relieved, and in thirty minutes all pain was gone. Saturated cloths were kept on the blistered parts all night, and next day the patient was perfectly well.

The reason the foregoing case is reported is that I have repeatedly heard of physicians who advised in such cases alkaline solutions to neutralize the carbolic acid. As a chemical fact, carbolic acid is not at all, being perfectly neutral in reaction; hence the futility of alkaline solutions. Sodium sulphate, however, forms with carbolic acid sulphocarbolate of sodium, which is soothing in effect and prevents the carbolic acid from doing further damage. This chemical antidote even Withaus fails to mention in his *Chemistry*.

Another reason for reporting this case is to call

forth caution in advising the use of carbolic acid by the laity. Carbolic acid is only very slightly soluble in water, and when poured into water does not dissolve or distribute itself, but falls to the bottom. In turning on the water, for instance, from the fountain syringe, the first thing that escapes is carbolic acid, but very slightly diluted, which may do much injury. In order to obtain a uniform distribution of the carbolic acid the mixture must be continually stirred or shaken.

740 SIXTH STREET.

Therapeutical Notes.

Musk Mixture.—P. Voier (*Journal de médecine de Paris*, November 27th) gives the following formula for a musk mixture, which in European countries is highly regarded as a stimulant and antispasmodic:

R Musk	15 grains;
Alcohol at 95	60 minims;
Syrup	450 "
Distilled water	1,500 "

Triturate the musk with the alcohol, and when it is reduced to an impalpable powder add little by little the water, and then the syrup. According to Foster's *Practical Therapeutics*, it is of value in typhoid diseases when there is subultus tendinum, muttering delirium or hiccough, without collapse or coma; in the adynamic pneumonia of drunkards with cerebral symptoms; in hiccough, laryngismus stridulus, spasmodic cough, pertussis, chorea, tetanus, hysterical convulsions, insomnia due to mental and bodily fatigue, and in threatened paralysis of respiration, as in the advanced stages of cholera infantum or meningitis. From five to fifteen grains may be administered at one dose.

A Local Application for Nasal Ulcers in Ozæna.—Professor Adolfo Fasano (*Archiv. o internazionale di medicina e chirurgia*, November 30th) recommends for topical use in the more or less deep ulcerations that are found in inveterate ozæna the following application:

R Aristol	450 grains;
Collodion	1,200 "
Castor oil	150 "

M. The application should be made daily by means of small cotton holders.

For Nervous Disturbances of Gastric Origin.—The *Clinica medica* (Nov. 1898) gives the following:

R Metallic potassium	11 grains;
Glycine acid, freshly prepared	11 grains;
Powder of opium, finely divided	of a grain
Boiled water	

In each powder. One powder to be given with each meal.

A Mixture for Menorrhagic Dysuria.—According to the *Practitioner* (or *Chirurgeon*), the following is the formula:

R Sodium phosphate	Four grains;
15 grains of water	
Water	
Four grains of opium	

M. S. A. (The *Practitioner* or *Chirurgeon*), Nov. 1898.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON AND COMPANY.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JANUARY 7, 1899.

A CHALLENGE TO "CHRISTIAN SCIENCE."

ACCORDING to the *New York Times* for December 28th, a woman was so badly burned at Omaha on December 24th by an explosion of boiling turpentine that she died on the 27th from the effects of her injuries. The family, being Christian Scientists, refused all medical assistance. Of course it is impossible to say whether in this case the patient would have fared any better had she received medical attention, for extensive burns are notoriously very fatal. But the following reflection occurs to us with great force. Medicine is admittedly dependent upon material laws, and is consequently subject to all the limitations imposed by those laws. But "Christian Science" asserts that matter has no real existence, wherefore material laws can have none either; they are figments of the imagination, ghosts so to speak, which will disappear under the power of mind. The injuries, therefore, being unreal, if this theory is true, they can have no magnitude, since there can be neither greater nor less in nought. Consequently the success of treatment ought to be just as certain in what appears to be the severest degree of burn as in what appears to be a trivial one.

In other words, "Christian Science" is what it purports to be or it is not. If it is, then there is *no excuse for failure in any case whatever*; if it is not, then it is pernicious in the highest degree and a public "pest," much as Mrs. Eddy may squirm under the term, since it forbids the use of even such limited therapeutic measures as medicine affords, which measures are beyond dispute in a large number of cases successful. There remains a third, and as we believe the true, hypothesis concerning "Christian Science"—viz., that it is a form of therapeutic "suggestion" or hypnotism, the religious basis serving merely as a means of arousing the initial faith requisite to make "suggestion" operative, which position is, however, vehemently repudiated by the "Christian Scientists" themselves. That position being true, then "Christian Science" would undoubtedly be limited by the ordinary limitations of suggestive therapeutics, which implies that it should be regarded as only one arrow out of the quiver of medicine, and used in such cases only as it is scientifically

applicable to, and by such people only as are possessed of sufficient knowledge of disease to know where and how far the treatment may be trusted, and to what extent it needs supplementing or replacing by other measures. On the first hypothesis every "Christian Science" failure is absolutely criminal and should be dealt with accordingly; on either of the two others the practice of it by unqualified persons is culpable, and its practitioners should be punished, whether successful or unsuccessful, under the medical laws, if they are not properly educated in the healing art as a whole.

Whatever latitude may be allowed to persons acting "out of affection" or from mere common humanity to the best of their knowledge and power, those who set up to be professional philanthropists, and no more mercenary and grasping specimens of that class have ever existed than those of the "Christian Science" cult, and who work for pay can claim no such exemption; and those principles of public protection which apply to all other members of the healing art should be rigidly enforced against them.

Once subject to the medical laws, and having been forced to prove to the satisfaction of the examiners that they possess an adequate knowledge of the structure and functions of the human body and of its varying conditions in health and disease, they would be at liberty to utilize "suggestion" according to their own methods, but with this proviso, that if they showed culpable ignorance or negligence in dealing with any case by employing measures wholly unfitted and inadequate to that particular case, they would be subject, as are all physicians for a flagrant misuse of the therapeutic means at their command, to an action for malpractice.

In another column in the present issue appears a transcript from a letter to the *Sun* by Dr. Charles A. L. Reed, of Cincinnati, in reference to Mrs. Eddy's address to the Christian world. It sweeps aside all sophistries and logomachy and, by directly challenging the truth of her statements as to matters of fact, brings the issue down to close quarters. If Mrs. Eddy has any faith at all in her cult beyond its properties as a big money-making scheme, Dr. Reed affords her in the most candid way an opportunity of demonstrating it under conditions which, while satisfactory as a test to her opponents, can leave nothing to be desired by any fair-minded disputant on the side whose position is here challenged. If Mrs. Eddy fails to take up this eminently fair-minded challenge, affording her that opportunity of demonstrating her position which she and her adherents profess so earnestly to desire, then she will stand convicted as the charlatan we at present believe her to be. If, on the other hand, she can practically

substantiate her claims to effect more than can be effected by ordinary lay hypnotists who base their position upon suggestion pure and simple, without any appeal to a religious platform, and can clearly prove that cases of organic disease with actual structural alteration can be cured by her methods, she will do more to establish her claims among all honest seekers after truth, whether medical or lay, than any amount of verbose and seemingly puerile quasi-metaphysics can possibly accomplish.

MR. RIDER HAGGARD'S *DOCTOR THERNE*.*

ONE need not be a partisan of compulsory vaccination to appreciate the tremendous harm which organized opposition to vaccination may bring about. How it may do this is admirably and dramatically set forth by Mr. Rider Haggard in his story entitled *Doctor Therne*. The story is told in the first person, and this has led Mr. Haggard into one or two slips in making Dr. Therne relate incidents that he could not have known about, at least in the particularity with which he tells them. That is the only fault we have to find with the book. In particular, we have nothing but praise for Mr. Haggard's accounts of medical matters, the well-known stumbling-block of the lay writer.

Dr. Therne, an uncommonly clever young physician, incurs the enmity of Sir John Bell, the leading practitioner of an English city in which he, Therne, has recently settled in practice. This he does by proving that Sir John has, by reason of negligence, not only mistaken a case of venous thrombosis for one of rheumatism, but actually caused the patient's death by insisting on a vigorous course of rubbing, whereby a portion of the clot is detached and carried into the pulmonary circulation. The open breach between Sir John and Therne seems to have been healed at last, and Sir John offers to attend Mrs. Therne in her approaching confinement. His offer is accepted, but the lady dies of puerperal fever. During her illness, and before he yet knows the nature or the gravity of it, Therne attends a titled lady, and she, too, dies of puerperal fever. Her husband brings a criminal prosecution for manslaughter against Therne, and Sir John Bell gives false testimony that is very damaging to the accused. The jury brings in a verdict amounting to "not proven," and Therne finds himself utterly discredited, destitute of resources, and threatened with a civil suit based on the same allegations as the criminal process had been, but this is discontinued.

In the preliminaries of the criminal trial a rich old crank goes bail for Therne. The old fellow is a rabid antivaccinationist, and he employs Therne to search out and report upon cases of the real or apparent injurious effects of vaccination. At last he induces him to run for parliament on the Liberal ticket in a borough where the Liberals' sole chance of success lies in a vigorous campaign on the antivaccination basis. Before that, Therne had done nothing dishonorable; now he enters upon a course of duplicity which ultimately ruins him. In reality, he is a thorough believer in vaccination, but, to show that his assumed opposition to compulsion is sincere and based on his aversion to vaccination, he shows the bare arms of his little daughter, four years old, which are destitute of vaccination marks, although the truth is that he had always meant to have her vaccinated, but had put off the little operation on account of the delicate state of her health.

Therne is elected to parliament and keeps his seat for twenty years. Finally an epidemic of small-pox befalls the borough, and his daughter, brought up in an atmosphere of active opposition to vaccination, has never been vaccinated. A young physician who has fallen in love with her finds that she has been exposed to small-pox, and begs her to let him vaccinate her, but, loyal to her father and his assumed convictions, she will not submit. In due time she comes down with the disease and, just as she is compelled to take to her death-bed, she comes upon her father in the dead of night secretly vaccinating himself. Shortly before her death she informs the young doctor of what she has witnessed.

The climax occurs that night at a political meeting. It would hardly be fair to the book for us to mention the dramatic scene with which it closes. We hope it will be read far and wide, especially by the honest people who have suffered themselves to be led into the antivaccination delusion.

MINOR PARAGRAPHS.

MORE ABOUT "THE ORION": A CORRECTION CORRECTED.

IN our issue for December 24th we said in a minor paragraph that we should like to know to what language the word "orion" belonged. We did not anticipate that our remark would be taken as a score as a request for information, but rather that it might cause those who were rusty in their Latin to refresh their memory by reference to a dictionary. One reply, however, written to us, *Galaxy*, Dec. 28, 1898, *Wash. M. T. Herald* for December 24th, proposed, very well and true to know to what language the word "orion" belongs. Answer: Latin. But the precise fate of the word is governed by the proposition that "Nomen est Verbum."

* *Doctor Therne*. By H. Rider Haggard. New York: London, and Bombay: Longmans, Green, & Co., 1898.

ori; accus., *orem*; abl., *ore*." We beg respectfully to inform our correspondent that *orem* is not the accusative case singular of *os*. *Os* is neuter, and its accusative case is, therefore, as in all Latin nouns, the same as its nominative. If our correspondent doubts our word we refer him to any Latin dictionary in proof of the first statement, and to any Latin grammar in proof of the second. There is a great deal too much bastard Latinity current in medical writing, and this does great harm to the claims of the medical faculty to a place among the "learned professions." Better use correct English than incorrect Latin.

THE LAW IN ITS RELATIONS TO MEDICAL MEN.

IN this issue of the *Journal* we begin the publication of a series of articles, by Mr. Taylor, which can not fail to prove instructive on many a point in which the law affects physicians. They are not on the subject of medical jurisprudence, it will be seen, but on the rights, duties, privileges, exemptions, and accountability of medical men under the law—topics concerning which the practitioner every now and then finds himself urgently in need of information. Mr. Taylor's articles will treat of them with the definite purpose in view of giving just that sort of information in language free from legal technicalities or with only such technical law expressions as are explained in the articles themselves.

AMPUTATION OF THE THIGH WITHOUT HÆMOSTASIS.

M. DESGUIN (*Gazette hebdomadaire de médecine et de chirurgie*, December 15th) reported recently to the Belgian Society of Surgery the case of a man twenty-four years of age in whom he amputated at the thigh after having applied Eschsch's band. At the end of the operation he did not tie a single vessel. He applied a slightly compressing dressing and placed the stump on an inclined plane. A cure was effected without any accidents, and union by first intention took place. M. Desguin cited this case to prove that it is possible in a great number of cases to sever even important vessels without any considerable hæmorrhage resulting. It is not, however, stated why so extraordinary a proceeding was considered desirable, the danger of which is recognized by the author himself when he remarks that the procedure is not an example which can be recommended for imitation in all cases.

THIOCOL.

DR. SCHWARTZ (*Gazzetta medica lombarda*, 1898, p. 275; *Gazette hebdomadaire de médecine et de chirurgie*, December 11th) proposes a new combination for tuberculosis, which he names thiocol. It is a sulphoguaiacolate of potassium and has the following formula:

100 c. c. of the following ingredients: 1. Iodurum mercurii, 2. Solubility in water, 3. Absence of any irritant effect upon mucous membranes, 4. Great facility of absorption. The preparation is said to be easily tolerated, and may be administered without inconvenience to the extent of from a hundred and fifty to two hundred and twenty-five grains daily. Under its influence the appetite is said to return, an amelioration of strength ensues, and the

patient gains flesh. The cough is diminished rapidly in intensity and frequency, the expectoration becomes less in quantity and less purulent, the night sweats disappear, and the general condition improves. Physically the pulmonary lesions appear to undergo arrest.

A NEW INTERNATIONAL PSYCHOLOGICAL JOURNAL.

WE have received the first number of *L'Intermédiaire des neurologistes et des aliénistes*, which is described as an *organe international trilingue de neurologie, psychiatrie, psycho-physiologie*. It is under the direction of Dr. Paul Sollier and is announced to be published on the 10th of each month. The first number, which now lies before us, is that of November 10, 1898. The principal feature consists in the reproduction of each article in French, German, and English. This number contains, first, the programme of the journal; secondly, a section of questions and replies; and finally, a summary of neurological and psychological journals published in the French, English, German, and Italian languages. In regard to the English version, while it is not in any sense obscure, there are a large number of translated idiotisms which mar its smoothness to the English reader. To give an instance, we may mention the constant use of the infinitive in place of the present participle in dependent sentences—e. g., "hinder many a practising physician to publish, etc.," instead of "from publishing." There must surely be in Paris some English physician who could be induced to collaborate by removing these idiotisms from the English translation, and thus render the excellent idea more perfect in execution. We wish every success to the new venture.

THE INJECTION OF ANTITETANUS SERUM INTO THE SUBARACHNOID SPACE.

THE interest felt in the treatment of grave cases of tetanus by the direct application of the antitoxine to the central nervous system is further exemplified in a communication recently made to one of the French medical societies by M. Étienne Martin, a hospital interne (*Lyon médical*, November 20th). A lad eighteen years old entered the hospital in Jabonlay's service, a week after having wounded his foot by stepping on a nail. On the day before his admission he had experienced difficulty in opening his jaws and in chewing. At the time of his admission there were generalized tetanic contractions, and he could scarcely speak. The cicatrix left by the wound was excised at once. Then lumbar puncture was practised with a large trocar. About ten cubic centimetres of absolutely clear liquid escaped, and a like amount of antitetanus serum was injected. The usual treatment with chloral and morphine was begun at the same time. That afternoon the lad died without having shown any amelioration. The reporter stated, however, that, notwithstanding the failure of the lumbar-puncture treatment in this case and in two others, one of his own and one of Brissaud's, M. Jabonlay would resort to it again, but immediately after the infection.

AN ATTEMPT TO PREVENT PHOSPHORUS POISONING AMONG WORKERS IN MATCH FACTORIES.

AN important advance in the manufacture of matches by two French engineers, M. Sève and M. Cahen (*Revue d'hygiène*, 1898; *Lyon médical*, November 20th). The matches, which have been on sale for several months,

are said to be perfectly satisfactory. The sesquisulphide of phosphorus is used in making them, a compound described as intermediate in properties between ordinary white phosphorus and red phosphorus. It gives off no fumes at usual temperatures and does not oxidize in the air; consequently the danger to the makers of these matches is reduced to the minimum that may result from direct absorption.

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 31, 1898:

DISEASES.	Week ending Dec. 24.		Week ending Dec. 31.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	20	12	18	9
Scarlet fever.....	141	12	141	11
Cerebro-spinal meningitis.....	0	6	0	11
Measles.....	123	6	142	9
Diphtheria.....	151	32	155	25
Croup.....	23	8	16	11
Tuberculosis.....	202	165	126	173
Small pox.....	1	0	3	0
Chicken-pox.....	0	0	11	0

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, cholera, and plague have been reported to the supervising surgeon-general of the United States Marine Hospital Service during the week ending December 30, 1898:

Small-pox—United States.

Pueblo, Col.....	Dec. 10-17.....	4 cases, 1 death.
Hillsboro, Kan.....	Dec. 24.....	9 "
(Reported as imported from Russia.)		
Newton, Kan.....	Dec. 21.....	2 cases, 1 death.
Seneca, Kan.....	Dec. 21.....	1 case.
(A member of the Seventh California Volunteers.)		
Louisville, Ky.....	Dec. 21.....	1 case.
(Origin not known.)		
New York, N. Y.....	Dec. 21.....	1 "
Guthrie, Oklahoma.....	Dec. 17.....	4 cases.
(Total to date, 5 cases.)		
Bedford, Pa.....	Dec. 20.....	9 "
Enid, Fulton County, Pa.....	Dec. 20.....	Reported present.
Robertdale, Huntingdon County, Pa.....	Dec. 20.....	Reported present.
Memphis, Tenn.....	Dec. 20.....	1 case.
Wilmington, N. C.....	Dec. 21.....	1 "
(Workmen employed on repairs at Marine Hospital station; origin of disease unknown.)		
Norfolk, Va.....	Dec. 21.....	7 cases.
(Unofficially reported that 5 cases were sent to County Pest House from the village of Berkeley.)		

Small pox—Foreign.

Antwerp, Belgium.....	Dec. 4-12.....	8 cases, 4 deaths.
Haifa, Brazil.....	Nov. 19-Dec. 3.....	43 " 3 "
Rio de Janeiro, Brazil.....	Nov. 4-18.....	20 " 11 "
Guayaquil, Ecuador.....	Nov. 4-12.....	9 " 1 death.
Bombay, India.....	Nov. 22-29.....	1 "
Rome, Italy.....	Nov. 5-12.....	1 "
Moscow, Russia.....	Nov. 25-Dec. 3.....	13 " 1 death.

Yellow Fever—Foreign.

Rio de Janeiro, Brazil.....	Nov. 4-18.....	8 cases, 5 deaths.
Vera Cruz, Mexico.....	Dec. 8-16.....	1 "

Plague.

Bombay, India.....	Nov. 15-21.....	2 deaths.
Bombay, India.....	Nov. 22-29.....	4 "
Madras, India.....	Nov. 19-25.....	1 death.

Cholera—Foreign.

Calcutta, India.....	Nov. 5-12.....	2 deaths.
Madras, India.....	Nov. 19-25.....	5 "

Japan.—During the period from October 21st to November 17th there were 9,746 cases of dysentery and 2,856 deaths. The entire empire now seems to be saturated with the poison of this disease, and its annual recurrence may be fairly anticipated.

The Medical Society of the County of Broome, N. Y.

—At the last quarterly meeting, held in Binghamton, on Tuesday, January 3d, the following papers were to be read: The X Ray. What can we do with it? by Dr. D. E. Cone; Hygiene, by Dr. I. A. Hix.

The Buffalo Academy of Medicine.

—At the last regular meeting of the Section in Surgery, on Tuesday evening, January 3d, the following papers were to be read: A Study of Protargol in Acute Gonorrhea, by Dr. George K. Swinburne; Burns, Scalds, and Frostbites, by Dr. A. E. Diehl.

What is Nature?—Dr. A. Jacobi (*Philadelphia Medical Journal*, December 24th), in an article on Some Preventives, makes the following sound remarks:

"Nature does not kill and does not heal. If there were consciousness in Nature, she would feel indifferent about what she is—viz., mere evolution. Nature is sunshine that grows harvests and sunstrokes; she makes moonshine for lovers and for burglars, and rain to feed men and to drown them, and the sun warms the unjust and the just. Nature is a Mauser bullet; stand in its way, you are hit; dodge, and you are saved—it makes no difference to Nature. In Nature a diphtheria bacillus has its democratic rights and duties like George Washington, and it killed him; she has no predilections, no reasoning; she is cause and effect. She can be led and doctored. The engineer heals her deformities in the interest of commerce; insurance companies correct her failures or calamities; indeed, the logical mind of man and the logical necessities of Nature are engaged in a constant strife for superiority. In matters of health and disease of *Homo sapiens* the doctor utilizes or combats the doings of Nature. By curing he cures. Curing has long ago lost its literal meaning. It is healing."

A New Method of inducing Premature Labor.—Spinnelli (*Gazzetta medica lombarda*, December 12th) described at the Congress of Obstetrics and Gynecology, in Turin, a new method of inducing premature labor, which consisted of introducing the index finger into the cervical canal, previously dilated in primiparae, and then passing beyond the internal orifice. The inferior portion of the membrane is then gently torn with the hooked finger, and by the guidance of the finger a strip of gauze impregnated with glycerate of ichthyl is inserted, which should be placed between the ruptured membrane and the lower segment of the uterus. This manœuvre can be executed by the drawing down of the uterus by means of a forceps applied to the lower part of the cervix. The vaginal canal is then closed with a sterilized gauze. Labor usually occurs in about four hours. The author described four cases, three of which resulted

Verdict of Manslaughter against a Faith Curist Upheld.—The Supreme Court of the State of New York, in the case of *The People vs. John J. Smith*, who was charged with the murder of a woman named Mrs. Justice, held that the verdict of manslaughter was proper.

in allowing her to die of pneumonia without asking medical advice. The case came up last week before the Court for Crown Cases Reserved, but the decision was unanimously upheld.

The Proper Way to Teach.—The *Philadelphia Medical Journal* for December 24th says:

"We have seen much of several schools and we are glad to say that in a few the secret of teaching has been learned. We recently accompanied one of these modern teachers as he went through his wards with his class. He gave no didactic lectures. He held recitations on the diseases that were not likely to be seen in the wards. Two hours daily he was in the hospital with his students and talked to them and showed them how to examine and what to look for, and they examined for themselves and took daily notes of the cases and at the post-mortem table saw what really was. He has learned the great lesson that the function of a teacher is to teach method, teach how to learn, and to give opportunity to learn, and not merely from the professorial chair say with the infallibility of a lay pope, This is so because I say it, and forget it at your peril, and never mind why it is so, and do not try to use your own eyes and ears and hands to find if verily it is true, but accept my authority. The secret of instruction is to teach methods, not results; to teach by demonstration, not by dictum."

Change of Address.—Dr. B. W. Brush, to Woodside, Long Island.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending December 29, 1898:*

WHEELER, W. A., Surgeon. To proceed to Cairo, Ill., and assume command of service. December 28, 1898.

KALLOCH, P. C., Surgeon. Upon being relieved by WHEELER, W. A., Surgeon, to proceed to Gulf Quarantine Station and assume command. December 28, 1898.

McINTOSH, W. P., Passed Assistant Surgeon. To report to the Director of the Hygienic Laboratory for a course of instruction. December 27, 1898.

SMITH, A. C., Passed Assistant Surgeon. Upon being relieved by KALLOCH, P. C., Surgeon, to proceed to Norfolk, Va., and assume command of service at that port. December 27, 1898.

EAGLE, J. M., Passed Assistant Surgeon. To report to Director of Hygienic Laboratory for a course of instruction. December 27, 1898.

NYBERG, E. A., Passed Assistant Surgeon. Granted four days leave. December 24, 1898.

STEWART, W. J., S., Passed Assistant Surgeon. To rejoin station, Washington, D. C., immediately. December 29, 1898.

HASTING, H. H., Assistant Surgeon. Upon being relieved, to report to Director of Hygienic Laboratory for a course of instruction. December 27, 1898.

RUSSELL, H. C., Assistant Surgeon. Upon being relieved by BOHANNON, D. E., Assistant Surgeon, to proceed to Louisville, Ky., for duty and assignment to quarters. December 27, 1898.

BILLINGS, W. C., Assistant Surgeon. To report to WHITE, J. H., Surgeon, Immigration Depot, New York, N. Y., for duty. December 27, 1898.

KERR, J. W., Assistant Surgeon. To report to medical officer in command at San Francisco, Cal., for duty and assignment to quarters. December 27, 1898.

ROBINSON, D. E., Assistant Surgeon. To report to medical officer in command at Chicago, Ill., for duty and assignment to quarters. December 27, 1898.

CORPUS, G. M., Assistant Surgeon. To assume command of Egmont Key Detention Camp. December 27, 1898.

STEVENSON, J. W., Acting Assistant Surgeon. To assume temporary charge of service at Cincinnati, Ohio. December 28, 1898.

Appointments.

To be assistant surgeons:

BILLINGS, WILLIAM CHESTER, of Massachusetts. December 23, 1898.

KERR, JOHN WALTER, of Ohio. December 23, 1898.

ROBINSON, DANA ELIHU, of Ohio. December 23, 1898.

CORPUS, GUSTAVE MAXIMILIAN, of Georgia. December 23, 1898.

Births, Marriages, and Deaths.

Married.

BOVAIRD—LASKER.—In Montreal, on Tuesday, December 27th, Dr. David Bovaird, Jr., and Miss Louise Lasker.

BROUGHTON—PINGREE.—In Jamaica Plain, Massachusetts, on Saturday, December 24th, Dr. Arthur N. Broughton and Miss Lilian DeW. Pingree.

BRUSH—FOSTER.—In New York, on Saturday, December 24th, Dr. B. W. Brush and Miss Mabel Hoyt Foster.

DRAPER—HOFFMAN.—In New York, on Wednesday, December 28th, Dr. William Kinnicutt Draper and Miss Helen Hoffman.

FRAMPTON—LUCAS.—In Wando, South Carolina, on Wednesday, December 14th, Dr. James Frampton, of Mount Pleasant, South Carolina, and Miss Elizabeth Buist Lucas.

LOTTERHOS—SAMPLE.—In Summit, Mississippi, on Tuesday, December 20th, Hon. F. H. Lotterhos and Miss Helen Sample, daughter of Dr. J. R. Sample.

MURPHY—MARCHEL.—In Mobile, Alabama, on Thursday, December 22d, Mr. Samuel S. Murphy, Jr., and Miss Marie Marchel, daughter of Dr. Edwin L. Marchel.

PRICE—DENNY.—In Boston, on Sunday, December 25th, Dr. Walter H. Price and Miss Nora L. Denny.

PRICE—WILLIAMS.—In Booneville, Mississippi, on Thursday, December 22d, Dr. John Wesley Price and Miss Hettie Williams.

SILCOCKS—SMITH.—In Watervliet, N. Y., on Wednesday, December 10th, Dr. William E. Silcocks and Miss Henrietta Smith.

WHITE—SCOTT.—In Chelsea, Massachusetts, on Wednesday, December 21st, Dr. E. L. White and Miss E. E. Scott.

Died.

BROWN.—In Noroton Heights, Connecticut, on Tuesday, January 2d, Dr. William G. Brownson, in the sixty-ninth year of his age.

EDDY.—In Greenville, Rhode Island, on Friday, December 16th, Mrs. Emily Tillinghast Eddy, wife of Dr. Elmer B. Eddy.

GUILLON.—In New York, on Sunday, January 1st, Dr. Charles F. Guillon, United States Navy, aged eighty-six years.

Special Articles.

THE LAW IN ITS RELATIONS TO PHYSICIANS.

By ARTHUR N. TAYLOR, LL. B.

I.

INTRODUCTION

Origin and Development of Our Laws.—Our system of laws, like our language, was brought with us from the mother country, where it had slowly developed during the centuries that saw the crude, barbaric Briton become the civilized and enlightened Englishman.

Like the Englishman of modern times, our law represents not alone development but also the reception and assimilation of foreign material from widely separated sources. When the Britons gave way to the more powerful Saxons the laws of the Druids commingled with and became a part of the Saxon laws and customs; the subsequent arrival of the Danes brought additional elements; afterward the invasion of the Romans, and finally the conquest of the Normans, brought much of the civil law of continental Europe and many customs foreign to those of our northern ancestors; among these was the feudal system upon which is based our present law of real estate. Not only was the law greatly changed in substance by this latest arrival, but in outward form as well, Norman-French being the language in which all public proceedings were recorded and in which the records of the courts were kept from the time of William I to that of Henry III. The Latin language was substituted by Henry III, and from that time the Law Latin was used until the fourth year of George II, except during the time of Cromwell, that sturdy character evidently deeming good, terse English a better medium for expressing the law of a great nation. It is undoubtedly by reason of this slow development and liberal admixture of elements from such widely separated sources that both our language and our system of laws have acquired their wonderful degree of flexibility that is shown in the readiness with which they meet the requirements of our constantly changing and developing conditions.

General Divisions of the Law.—Our laws are divided into two kinds—the common law, or *lex non scripta*, and the statute law, or *lex scripta*.

Common Law Described.—The Latin names of these two general divisions of the law are in a measure historically descriptive, the *lex non scripta*, or common law, being those general and particular customs which have existed time out of mind, or, according to the ancient legal expression, "time whereof the memory of man runneth not to the contrary," undoubtedly not their origin at a time when writing was unknown in western Europe, some of them being said to be derived from the Gallic Druids. Blackstone, who wrote at about the middle of the eighteenth century, describing the common law, said: "This is that law by which the Romans, and the

terminations in the king's ordinary courts of justice are guided and directed. This, for the most part, settles the course in which lands descend by inheritance; the manner and form of acquiring and transferring property; the solemnities and obligations of contracts; the rules of expounding wills, deeds, and acts of parliament: the respective remedies of civil injuries; the several species of temporal offenses; and the manner and degree of punishment: and an infinite number of minute particulars which diffuse themselves as extensively as the ordinary distribution of common justice requires." * It was to this branch of the law that Lord Coke referred when he said: "Reason is the soul of the law; and when the reason of any particular law ceases, so does the law itself." † Such a system of law, it will be observed, can not be reduced to writing in the form of a code without having its entire nature changed. The universal application of the principles and customs of which it consists would be destroyed, and the system would become crystallized into a set of fixed rules incapable of organic growth and development. There is, however, some method of recording necessary to secure stability and certainty to this branch of the law, and this is accomplished by preserving the records of the courts of highest jurisdiction, which show the history of each case determined and illustrate the application of the principles of law governing it. These records are kept as precedents to guide the courts in the future application of law to similar facts coming before them for adjudication.

Common Law of the United States.—The common law of England was not found to be entirely suited to the altered conditions on this side of the Atlantic, and was therefore only adopted so far as it was applicable to our situation. The term common law as used in the United States may be generally said to include all of the law of England existing at the time of the settlement of the colonies which was found applicable to our conditions.

In contemplating the great age of our common law and the identity of its development with that of our parent nation, one can not help regarding it with a feeling of veneration and sympathizing with the Mississippi lawyer who, upon seeing the common-law rights of dower † and coverture[§] wiped out by the legislature of his State, exclaimed: "Venerable relics of antiquity, you have come down to us from a former generation. You have survived the wreck of empires and change of dynasties. Born way back in the womb of Time, whereof the memory of man runneth not to the contrary, you have outlived the War of the Roses, crossed safely through the Protectorate, crossed the ocean, survived the great American Revolution, and rode out the storm of the late great war. What or attendants were absent from the birth of Adam, you two at least were always there; and when the first Adam gave up mortally murmured, 'With all my worldly goods I do leave you,' you, as priest and priestess, so held your ground. The shades you've followed the twin blood of humanity, and wherever

* $\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{i=1}^n f(x_i) = \int_a^b f(x) dx$.

400 *Journal of Interpersonal Violence*

either fell one of you administered the balm of consolation to the survivor. If pure religion and undefiled be to visit the fatherless and the widow in their affliction, thy mission has been akin to it. Venerable priest and priestess of the common law, farewell! You have been pleasant in your lives, and in your death have not been divided."²²

Statute Law.—The statute law, or *lex scripta*, consists in England of all of the enactments of parliament, or, as an English writer of the eighteenth century, more in the courtly language of the times, said, it consists of those "statutes, acts, and edicts made by the king's majesty, by and with the advice and consent of the lords spiritual and temporal, and commons in parliament assembled." In the United States the statute law includes all positive enactments of the various legislative bodies.

Whenever a question arises as to the application of a statute to a given condition not coming clearly within the purport of its meaning, the aid of the common law is invoked by the courts in interpreting and construing the act; it therefore will be seen that the common law forms the fundamental groundwork of our entire system.

Reason the Foundation of Law.—Reason being the soul of our law, as very aptly stated by Lord Coke, it necessarily follows that a clear comprehension of the law is based upon a knowledge of the reason underlying the law, and that one can not really know the law without first knowing the reason therefor.

In writing these articles the author will endeavor to keep this fundamental truth in mind, and will, whenever possible, first develop the general principle, giving the reason supporting the same, and then illustrate its application by particular cases. Whenever that course seems impracticable, he will endeavor to show the principle governing in the particular case and the reason for its application.

Book Notices.

Manual of Diseases of Children. By JOHN MADISON TAYLOR, A. M., M. D., Professor of Diseases of Children, Philadelphia Polyclinic, etc., and WILLIAM H. WELLS, M. D., Adjunct Professor of Obstetrics and Diseases of Infancy in the Philadelphia Polyclinic, etc. Illustrated. Philadelphia: P. Blakiston's Son & Co., 1898. Pp. xii-17 to 713. [Price, \$1.]

According to the statement of the authors in the preface, the book is not a treatise on the diseases of children, and they "do not attempt to offer much that is original or novel, and only obtrude their individual views when commenting upon the opinions of the great masters in the field of pediatric medicine."

The book is divided into twenty chapters. It is compact in its form, of convenient size, and well printed, and contains twenty-five illustrations, the majority of which are of great and show clinical types of disease. Examination of the book confirms the statement made in the preface that the authors have little or nothing

new to say on the subject of pediatrics. It appears to be largely an abstract or condensation made up from three of our latest books, those by Starr, Rotch, and Holt. These are all extensively quoted, the quotations sometimes covering pages.

The aim to give to medical students a condensed manual which represents fairly well pediatric opinion in this country has been, we think, achieved. Practitioners of medicine, however, will find it, we believe, too brief to be very satisfactory. As an illustration of the way treatment is discussed in many diseases, the following may be cited, referring to incontinence of urine, page 281: "In diseases attended by congestions, the use of ergot has been recommended. Cold douches to the perineum and faradism have been of some use. The passage of the cold sound in boys is recommended. Urethral electrization is often efficacious. Increasing doses of atropine or hyoscyne hydrobromate is the most reliable measure."

There are a good many minor defects indicative of carelessness in preparation; for example, there are two articles on retropharyngeal abscess, one on page 163 and one on page 400. On page 163 the disease is described as a lymphadenitis; on page 400, it is said to be an inflammation situated beneath the mucous membrane. The book abounds in coined words.

On the whole, we think the book will find a useful place with students in medical schools, but it can hardly supplant any of the leading treatises above referred to, for those who desire to get their knowledge at first hand.

An American Text-book of the Diseases of Children.

Including Special Chapters on Essential Surgical Subjects; Orthopædics; Diseases of the Eye, Ear, Nose, and Throat; Diseases of the Skin; and on the Diet, Hygiene, and General Management of Children. By American Teachers. Edited by LOUIS STARR, M. D., Consulting Pediatricist to the Maternity Hospital, Philadelphia, etc.; assisted by THOMPSON S. WESTCOTT, M. D., Instructor in Diseases of Children, University of Pennsylvania, etc. Second Edition, revised. Philadelphia: W. B. Saunders, 1898. Pp. xvi-1244. [Price, \$7.]

In its second edition this work is essentially a reproduction of the first, which appeared in 1894. There are some slight changes in the arrangement and new articles have been introduced upon modified milk and percentage milk mixtures, lithæmia, orthopædies, tuberculous meningitis, hydrocephalus, and typhoid fever.

The article on modified milk, by Dr. Westcott, is clear, concise, and in every way commendable; that on lithæmia, by Dr. B. K. Rachford, is an excellent one. The section on orthopædies comprises thirty pages and is from the pen of Dr. James E. Moore. It is necessarily very brief, too brief in fact to add much to the value of the book for the general practitioner. It is to be regretted that a more thorough revision of the article on diphtheria was not made. Of the eight pages devoted to treatment, only one is given to antitoxine, and so much in the way of other treatment is advised that a wrong impression is conveyed to the reader of the real place that antitoxine holds, even in the mind of the author; for, according to his own experience, which he cites, he is certainly a strong believer in its efficacy. It seems a serious omission, also, not to have incorporated in the article on cerebro spinal meningitis the recent discoveries in its etiology. This chapter appears unchanged.

* *Supplies of an of the*, November, 1890, from *Annotated Code of Mass.* 1893.

The new matter introduced has increased the size of the book by about fifty pages. It would, in our opinion, have been better had the revision included an abbreviation of some of the unnecessarily long articles, instead of making the volume, already very large, still more unwieldy in its size.

Essentials of Materia Medica, Therapeutics, and Prescription Writing, arranged in the Form of Questions and Answers, prepared especially for Students of Medicine. By HENRY MORRIS, M. D., Fellow of the College of Physicians of Philadelphia, etc. Fifth Edition, revised and enlarged. (Saunders's Question Compends, No. 7.) Philadelphia: W. B. Saunders, 1898. Pp. 16-288. [Price, \$1.]

THAT this work has passed through five editions is sufficient proof of its popularity. The new edition has been carefully revised, some obsolete matter has been omitted, and some additions have been made, particularly relating to the newer drugs. The doses are expressed in the metric as well as in the apothecaries' system, and this will add to the usefulness of the book.

While we believe that the author is right in making some classification of drugs as an aid to the student's memory, we must confess to a slight mental shock at finding antipyrine mentioned among the mydriatics and cod-liver oil among the aphrodisiacs. It should be said, however, that they receive only a passing notice in these connections. The new edition will doubtless retain the popular favor of its predecessors.

A Clinical Manual of Skin Diseases. With Special Reference to Diagnosis and Treatment. For the Use of Students and General Practitioners. By W. A. HARDWAY, M. D., A. M., Professor of Diseases of the Skin and Syphilis in the Missouri Medical College, St. Louis, etc. Second Edition, revised and enlarged. With Forty-two Engravings and Two Plates. Philadelphia and New York: Lea Brothers & Co., 1898. Pp. xii-17 to 557.

THE second edition of Dr. Hardway's book can not but receive the praise which is its due, inasmuch as it presents in a concise and clear manner the clinical and symptomatic features characterizing cutaneous diseases. It does not, fortunately, confine its description of the etiology, symptomatology, pathology, and treatment of these affections to the limits of the compendiums which appear so frequently, and which impart only the narrowest and barest knowledge of the subject to those who depend upon them, but it enters practically and thoroughly enough into each division mentioned to enable one to obtain not only a fair understanding, but also a desire to know more about them. In Part I the symptomatology, diagnosis, treatment, etc., are dealt with in general, while Part II contains the different classes into which the author has placed the various forms of skin diseases. In his classification Hardway has followed Hebra as modified by Crocker, and his Class I contains inflammations. Under this heading are included, among others, the various forms of erythema, eczema, herpes, pemphigus, eczema, urticaria, lichen, gangrene, dermatitis of various origin, etc. Class II is represented by hemorrhage, and then come successively hypertrophies, atrophies, new growths, neuroses, diseases of the appendages—glands, hair, nails—and lastly parasitic diseases. In these eight classes he includes all the

common diseases of the skin and a great many of the unusual or rarer forms, so that there can be found in the book a guide to almost any of the diseases of the skin.

As regards the descriptive part of the *Manual*, it can only be said that it is clear, comprehensive, and distinct, and the portions devoted to treatment are forcible and replete with valuable suggestions. It can certainly be frankly recommended to those who desire to know something about the affections occurring upon the skin, and will prove satisfactory to the busy practitioner, especially, who thinks not so much of the science of dermatology as he does of the diagnosis of his patient's disease and the way to get it well.

A Manual of Venereal Diseases. By JAMES R. HAYDEN, M. D., Chief of Clinic and Instructor in Venereal and Genito-urinary Diseases at the College of Physicians and Surgeons, New York, etc. With Fifty-four Illustrations. Philadelphia: Lea Brothers and Company, 1898. Pp. ix-17 to 304. [Price, \$1.50.]

THIS edition, like its predecessor, gives a summary of the pathology, symptoms, and treatment of the three venereal diseases, gonorrhea, chancroid, and syphilis, with their complications and sequelae. It shows evidence of a thorough revision, and the addition of a chapter on the care and use of medical instruments, containing a few brief but exceedingly pertinent rules, will make the work even more useful than it was before.

International Clinics. A Quarterly of Clinical Lectures on Medicine, Neurology, Surgery, Gynecology, Obstetrics, Ophthalmology, Laryngology, Pharyngology, Rhinology, Otology, and Dermatology, and Specially Prepared Articles on Treatment and Drugs. By Professors and Lecturers in the Leading Colleges of the United States, Germany, Austria, France, Great Britain, and Canada. Edited by JEROME DEXANDER, M. D. (Univ. of Pa.), Instructor in Clinical Medicine and Lecturer on Physical Diagnosis in the University of Pennsylvania, etc.; J. MITCHELL BRUCE, M. D., F. R. C. P., London, Physician to and Lecturer on the Principles and Practice of Medicine in the Charing Cross Hospital; and DAVID W. FENLAY, M. D., F. R. C. P., Aberdeen, Professor of Practice of Medicine in the University of Aberdeen, etc. Volume III. Eighth Series. Philadelphia: J. B. Lippincott Company, 1898. Pp. ix-355.

THIS volume opens with an article by Braden on the therapeutic use of alcohol, in which he urges the use of the undiluted drug, instead of wines, etc., and gives some account of the composition of the so-called fluid malt preparations. The lectures upon the treatment of tuberculosis, by Professor Gröber, to which we have alluded before, are continued. A lecture on some forms of abdominal pain, by Lander Brunton, and one on mitral stenosis, by Graham Steel, together with the consideration of some of the commoner medical children's diseases, by Trendelenburg, form the most important factors in the volume. In medicine the chapter that attracts most attention is that upon the treatment of cancer, by Trendelenburg, and the operation, by Moore, and the treatment of the constitutional causes of heart and B. disease, by Trendelenburg.

lecture on the two forms of chronic non-suppurative disease of the middle ear, hypertrophic catarrhal and sclerotic, or adhesive, inflammation.

Miscellany.

Mucomembranous Enteritis during Pregnancy.—M. Poizat (*Gazette hebdomadaire de médecine et de chirurgie*, November 24th) reported to the Congress of Gynaecology, Obstetrics, and Padiatry at Marseilles a case of mucomembranous enteritis commencing at about seven months and a half of the pregnancy, disappearing after delivery, and reappearing in a milder form during a second pregnancy. The author insists that there were no pathological antecedents, no neuropathy, no habitual constipation, no marked dyspeptic troubles. He does not consider the nature of this form of enteritis as different from that occurring in daily practice, the overproduction of intestinal fermentation being the principal exciting factor. This toxæmia may be the consequence of the constipation, which is common in pregnant women. The enteritis, though not rare in pregnancy, is often overlooked in the phenomena to which it has given rise. The microbic element ever present in mucous membranes is alone able to explain the infection. M. Vinay thinks that the condition is rare and can often be traced to intestinal paresis consequent on impregnation; but self-intoxication and a peculiar nervous state are two leading factors of the entire pathology of pregnancy.

The Carbolic-acid Treatment of Typhoid in India.—Captain R. C. Thacker, Royal Army Medical Corps (*British Medical Journal*, September 24th), gives his results of this treatment in the typhoid wards of the General Hospital, Nowshera. Seventy-nine cases were treated, with eleven deaths, giving the average mortality of 13.9 per cent. All the cases were diagnosed four times over by different officers. The treatment was as follows:

On the arrival of the convoy of patients from the railway station they were invariably at once seen and examined, after being thoroughly washed and cleansed and placed on a comfortable spring mattress with clean sheets and body linen. Carbolic acid was then prescribed; four doses of four minims each, well diluted with iced water, were ordered in the twenty-four hours. This was supplemented during the night, if the skin was hot and burning and the temperature running high, by two full doses of ordinary diaphoretic mixture. The formula generally used for the carbolic acid was Calvert's pure carbolic acid, four minims; spirits of chloroform, fifteen minims; compound tincture of cardamom, twenty minims; with syrup and water to one fluid ounce. This mixture was kept in the ice box, and was thus administered cool and refreshing to the sufferers. Without any exception it was well tolerated by the stomach, caused no unpleasant symptoms, and was thoroughly liked by the patients as a palatable medicine. In fact, in more than one instance it was reported by the sister on duty that the patients frequently asked for an extra dose. This, though a trivial incident, showed that the medicine was liked, and that the patient had some faith in its efficacy, a point of no small importance when treating soldier patients.

Dietary. The principal article of diet consisted of

three pints of fresh-boiled milk of excellent and irreplaceable quality in the twenty-four hours; five ounces were given every two hours, and were supplemented by a pint of sound, carefully prepared chicken broth. Two pints of iced barley water flavored with lemon were also allowed as a cooling drink (four ounces every hour) if so desired. The enteric evacuations were examined daily with care, and on the first suspicion of "solid" curd appearing in the stools, or the slightest tendency to irritability of the stomach, the milk was either peptonized or alkalinized, the latter being usually carried out by the sister on duty by adding a powder containing sodium bicarbonate, potassium bicarbonate, and sodium chloride, of each six grains to each pint of milk. This simple procedure proved most beneficial and effectual in many cases.

Stimulants.—Owing to the weak and prostrate condition of many of the patients on arrival, brandy had in most cases to be administered early in small quantities freely diluted. If grave symptoms supervened, such as a dry, brown, tremulous tongue; quick, weak, and irregular pulse; rapidly failing first sound of the heart, and low muttering delirium, the amount was rapidly increased up to eight or ten ounces in the twenty-four hours, with a pint of champagne if necessary and indicated. Stimulants in grave and malignant cases of typhoid fever in India are, in the author's experience, well borne by the patient, and in most cases are essential to a thorough and sound convalescence.

Complications, the author regrets to say, were frequent and severe. Cardiac asthenia, hypostatic congestion of the lungs, hyperpyrexia, perforation, secondary bronchitis and pneumonia, tympanites, nervous symptoms, phlegmasia, and four cases of hemorrhage are enumerated. The treatment of these complications was as follows:

Hæmorrhage.—The quantity of milk given every two hours was at once reduced to half, and given iced; stimulants were stopped altogether if admissible, or at least reduced to a minimum. Ice in small quantities was given to suck and allay thirst; ice was applied over the right iliac fossa and abdomen generally by means of ice trays. An enema in the ward of Dover's powder, ten grains, tannic acid, twenty grains, in two ounces of mucilage of starch, which was kept ready, was administered. At the same time a mixture composed of gallic acid, aromatic sulphuric acid, and liquor opii sedativus was given by the mouth every hour for six doses if necessary. This method was introduced by Dr. Burney Yeo, who stated that "lives had been saved by the precaution of having it kept ready at hand," and the author quite endorsed his opinion. Turpentine was freely used in cases of protracted hæmorrhage, and found most beneficial. A combination of turpentine, fifteen minims, with ergotin, three grains, and ten minims of liquor opii sedativus was usually prescribed. Ergotinine was also given hypodermically in doses of $\frac{1}{100}$ grain every fourth hour.

Cardiac Asthenia.—Cardiac asthenia with hypostatic congestion of the lungs proved a most frequent, dangerous, and trying complication to deal with, owing to its sudden onset and rapidly fatal termination. Stimulants were given freely, and also combined with tincture of digitalis, ten minims, and liquor strychninæ, three minims, in half an ounce of brandy freely diluted. The most satisfactory results were obtained from the hypodermic injection of strychnine in doses of $\frac{1}{60}$ of a grain every four hours until some improvement was observed

in the first sound of the heart and in the pulse. The author has no hesitation in saying that many lives were saved by these injections of strychnine. In many of the cases it had to be exhibited from the first day of admission.

Hyperpyrexia.—Hyperpyrexia caused anxiety in several cases. It was treated by ice sponging, ice pack, ice to the head and neck, with ice trays suspended over the abdomen; and internally mistura diaphoretica, with small doses of potassium bromide. Powerful antipyretics were carefully avoided, owing to their depressing effects on the circulation.

Secondary Bronchitis and Pneumonia.—These complications were usually treated with diffusible stimulants and expectorants; counter-irritation by means of mustard and linseed-meal poultices, turpentine fomentations, and dry cupping.

Tympanites.—Tympanites was rare, and occurred in very few cases to anything like an excessive extent. It was readily controlled by the ice cradles suspended over the abdomen. Hot flannel stupes of turpentine and opium liniment also were used, and internally oil of turpentine in ten-minim doses every fourth hour.

Diarrhea.—Excessive diarrhoea gave very little trouble and caused no anxiety; it was easily controlled by ordinary astringents, while the amount of milk was diminished, peptonized, or alkalized as the symptoms indicated.

Nervous Symptoms.—Nervous symptoms in the majority of cases were slight and quickly yielded to opium, potassium bromide, and tincture of hyoscyamus judiciously administered.

Phlegmasia.—Phlegmasia occurred in four cases; the foot of the bed was elevated and the affected limb painted with equal parts of glycerin and belladonna liniment and then wrapped in cotton wool kept in position with a wide flannel bandage.

The author concludes with the following remarks:

The following favorable signs appeared after the administration of the acid:

1. A rapid cleaning of the tongue with the abolition of the characteristic unpleasant typhoid odor from the breath.

2. A sustained and remarkable lowering of the febrile temperature with a well-marked morning remission in many cases.

3. Marked improvement in the unpleasant odor from the stools, which in a few days became practically odorized.

4. Tympanites, diarrhoea, and delirium were rarely excessive and easily under control.

5. A most favorable convalescence with a sound recovery.

Solomon Right Again.—The *Indian Lancet* for November 16th quotes the following:

"In *Notes and Queries*," says the *New York Times*, "there is a story quoted written by Mir Muhammad Masum in 1660. An exiled prince meets a man who is carrying what are designated as 'hakku tubes.' Looking at the man, the prince discovers that just as long as the man holds the hakku tubes his entire interior economy is visible. The prince at once purchases the tubes. Coming to Ghuzni, he finds a patient. The King of Ghuzni is suffering from dyspepsia. There is good reason for the king feeling so uncomfortable, for when the hakku tubing is applied, it is discovered that the patient had swallowed not less than two water snakes."

Readers will then please observe that the X rays have been anticipated. The original of the story is found in Elliot's *History of India* by its own history. After a while we may discover that Noah's ark had water-tight bulkheads and twin screws."

Antistreptococcus Serum in Chaneroid.—Mr. James Moore, F.R.C.S. Edin. (*British Medical Journal*, November 26th), states that during the past eight months he has used antistreptococcus serum in forty-eight cases of acute inflammatory bubo, and in only seven cases did suppuration occur. He records two very interesting cases. From his experience with antistreptococcus serum in venereal sores and their complications, he has arrived at the following conclusion:

1. While recognizing the great importance of early local antiseptic treatment of the chaneroid, he believes that if five cubic centimetres of the serum are injected subcutaneously into each inguinal region in cases in which inflammatory bubo is likely to develop, it will prove a good prophylactic measure, and assist in healing the chaneroid.

2. If inflammatory bubo has already developed, and the acute inflammatory symptoms have not been present more than forty-eight hours, ten cubic centimetres injected into the inguinal region corresponding to the inflamed gland will cause resolution in the majority of cases.

3. If there is evidence of pus formation the serum may possibly limit the extension of the suppuration, but in this class of cases his results have been anything but satisfactory.

4. The serum should always be injected into the area drained by the infected gland, preferably the right and left inguinal region. He has not seen good results by injecting it into remote areas.

5. In phagedenic ulceration complicating venereal sores this serum would appear not only to neutralize the toxins in the blood, but also to bring about a healthy condition of the ulcer.

The Excision of Carbuncles.—Mr. Rushton Parker (*British Medical Journal*, November 26th) again calls attention to the subject of the complete extirpation of carbuncles. "The ordinary methods of palliative expectation and excision, in his opinion, in which Sir James Paget in his *Clinical Lectures* seems to concur, show no advantage of one course over the other. The two principal features of carbuncles are (1) pain and (2) liability to septic poisoning. Incision, he asserts, does not relieve the pain, and does nothing to prevent or arrest septic poisoning. It is a severe operation, requiring an anæsthetic, and is itself liable to be followed by septic poisoning through newly opened channels.

The case is quite different, he continues, with extirpation, which, however extensive, is not a much more severe operation than incision. But what a contrast in the result! Ask a patient the difference between what he thinks of it, and he replies, "I feel no pain whatever, only a little weariness." "I feel as if a load had been taken off me." The carbuncle is then excised, flamed, stretched, and antiseptic treatments, with a thorough extirpation are all that is needed, leaving only a wound in healthy tissue. It is a simple method of avoiding septic poisoning, which at present is really a life-long confinement to the patient's bed. When the patient is the person to be benefited, it is a simple and safe operation.

The extirpation of carbuncles is a simple operation, according to the foregoing, and is a most effective

just as rational as the excision of tuberculous glands, the scraping of lupus, and the removal of sloughs, while experience amply proves its value. Among the twelve cases hitherto reported by him, two were in women, situated on the face; the rest were in men. In one or two cases the relief to pain was not complete, and this he attributes to insufficient thoroughness in the excision. If the carbuncle is very soft there may be a temptation to rely on thorough scraping alone, and so to leave some of the disease behind. It is advisable to remove all, and to thoroughly cut away with knife or scissors what can not be scraped.

He then reports five more cases, of which one proved fatal. This he attributes to not critically watching the sore to detect any reappearance of the carbuncular process, and not removing thoroughly all recognizable diseased parts. Diseased spots he touches with pure carbolic acid which effectually renders them aseptic and is at the same time anodyne.

Bichromate of Potassium in the Treatment of Chronic Gastric Ulcer.—Dr. T. McHardy (*Scottish Medical and Surgical Journal* for December) refers to the researches of Professor Fraser, of Edinburgh, on the value of bichromate of potassium in chronic gastric disease, and records the case of a woman under his care who had suffered from chronic gastric ulcer for twenty years. She had been bedridden for a year; the stomach was very irritable, rebelling on the most trifling indiscretion in diet. Epigastric pain was so severe as to demand constant recourse to morphine. Vomiting and hæmatemesis accompanied all ingestion of food, and nutrition had to be accomplished *per anum*. Anæmia and emaciation were marked, there was anxiety, with quick, weak, and irregular pulse, and dry coated tongue. Flatulence and constipation, with dry, hard stools of a very dark color, were present, often containing bloody mucus. The abdomen was tense and distended, the stomach dilated and very tender on pressure, and a distinct peristaltic action could be felt extending from the fundus to the pylorus.

Pain was referred to two circumscribed spots, each about the size of a dime, lying over the smaller curvature, and often shooting through to the back, especially to the left of the last dorsal vertebra. Occasionally pain became more widely distributed, and, when flatulence was severe, it extended into the scapular and clavicular regions. As food had been withheld for some days, the vomited matter contained only blood and mucus, which threw out a sour, disagreeable odor, and gave a strongly acid reaction.

To get rid of the mucus, and render the stomach as empty as possible, he first washed it out with a weak solution of boric acid. This had the direct effect of increasing the hæmorrhage, but after a subcutaneous injection of ergotin, and the application of an ice-bag to the epigastrium, this symptom quickly subsided. On May 11, 1897, he first administered a sixteenth of a grain of bichromate of potassium, dissolved in an ounce of distilled water. This was immediately followed by such violent pain and sickness that he was reluctantly compelled to seek relief by an injection of morphine. After an interval of six hours, the bichromate treatment was renewed, and on this occasion he observed a decided improvement in the consequent pain and sickness, and although these unpleasant consequences continued to follow each successive dose for a time, still, he noted a gradual abatement in their duration and in

tensity up to the fifth day, when the pain completely ceased. The sickness, however, persisted during the following week, but in a greatly modified degree. On the 18th of May the dose was increased to a twelfth of a grain, and administered every sixth hour as formerly. This was continued up to June 8th, by which date the entire group of gastric symptoms had entirely subsided.

As it was now evident that the anæmia had in no way benefited by the treatment, carbonate of iron and a solution of red marrow were substituted for the potassium salt. Under this the anæmia rapidly disappeared, and, after being continued for a month, the only remaining symptom was constipation. As the stomach at first rejected every form of nourishment given, feeding by nutrient enemata was maintained for a week. She was then allowed a tablespoonful of milk and lime-water, repeated every half hour. After some days, milk-arrowroot, yolk of egg, and bread pap were cautiously added to the dietary, and at the end of six weeks she was permitted to share the common food of the family. On visiting her on the 12th of February last I found her in excellent health and spirits. Her gastric troubles, with the exception of a mild form of indigestion, had never recurred. Her bodily weight had increased three stones, and she could discharge with comfort her usual household duties.

The author calls attention to the fact that vomiting, which previously had been a most distressing symptom, ceased after the first dose of the bichromate. This result he has experienced in other cases, and in a recent case of chronic gastritis with persistent vomiting, which had defied several different forms of treatment, its administration was attended by the happiest results.

Fictitious Appendicular Inflammation.—We hear so much of the treatment of appendicular inflammation nowadays, what with the advocates of delay and those of operation immediately on diagnosis, that it may be a useful caution to call attention to conditions liable to be mistaken for that disease. Dr. Donald Rood (*Clinical Journal*, December 14th) quotes the following case from his clinic in the West London Hospital: "This child, while walking, was tripped up by a man and fell. He complained of pain in the abdomen, and on examining him I found that he had swelling in the appendicular region on the right side. Here the swelling ran up from the brim of the pelvis, encroaching upon the iliac region. I did not think the trouble in this case was due to the appendix, but to cellulitis set up by definite strain. He has now been in a week, and nearly the whole swelling has disappeared; there remains only a small portion of infiltrated tissue."

The Curability of Pulmonary Tuberculosis by Intensive Mineralization.—Dr. N. Dimitropol, of Bucharest (*Gazette hebdomadaire de médecine et de chirurgie*, July 17, 1898), says that the ætiological study of pulmonary tuberculosis shows that the most favorable soil for the development of Koch's bacillus is that in which there is a deficiency of those organic and chemical elements which by combining with albuminoids insure the resistance of the organism. Consequently the treatment which, according to Dr. Dimitropol, is at the same time the most rational and the most efficacious, resolves itself into an intensive mineralization of the organism combined with substantial alimentation both natural and artificial. It is only by this means that one can build up the broken down economy of a tuberculous subject and not only prevent the lungs from becoming further

tuberculous, but favor also the sclerotic or cretaceous cicatrization of the part attacked.

The following is Dr. Dimitropol's mode of treatment. The patient is given daily, for thirty or forty days, each morning a nutritive mixture composed thus:

- ℞ Yolk of eggs 4 or 5 in number;
Pepsin 15 grains;
Hot milk 12½ ounces;

the whole being well beaten up for five minutes and flavored, according to taste, with a little vanilla.

Ten minutes later a slice of bread and butter well salted to the extent of at least half a teaspoonful of kitchen salt, and weighing about twelve ounces and a half, is given. When the patients are very wasted, there should be administered, in addition, nutrient enemata composed as follows:

- ℞ Yolk of eggs 4 in number;
Liquid peptone 37½ grains;
Chloride of sodium 75 "
Hot concentrated bou-
illon 1,200 to 1,500 grains.

This enema, well beaten up, should be slowly introduced by means of an irrigator. Each enema should be preceded by an evacuating enema.

The patient takes daily, moreover, from ninety to a hundred and eighty grains of tribasic phosphate of calcium and from thirty to sixty grains of phosphate of sodium, as in the following formula:

- ℞ Tribasic phosphate of calcium .. 30 grains;
Phosphate of sodium 7½ "

in each powder. From three to six daily.

After each meal the patient must also take in half a glass of water from two to four teaspoonfuls of hydrochlorophosphate of calcium in ten-per-cent. solution.

All the drugs enumerated should be administered in a graduated manner for forty days; toward the end of this time it is necessary to diminish the dose and to continue for six months and to recommence later with intermissions of fifteen days a month.

Further, there is prescribed daily for thirty or forty days two hundred and twenty-five grains of common salt mixed with food already salted in the ordinary culinary preparation. It is necessary for the patients to take indefinitely from ninety to a hundred and twenty grains of salt daily.

For diet from sixteen to eighteen ounces of meat, a quart of milk, three eggs prepared to the patient's taste, fish and vegetables in habitual quantity, but chosen by preference from among those most rich in nitrogen, such as lentils, haricots, peas, etc.

Such is in general lines the treatment of the Roumanian physician; it rests with the physician to apply it according to the stage of the disease, the age and constitution of the subject, taking care to proceed gradually in every case, and to keep always in view the tolerance of the patient both as regards alimentation, natural and artificial, and mineral treatment. The same mode of treatment may be employed in the case of mere serofulous and lymphatic subjects, excluding the artificial alimentation. Excellent results are claimed for it.

The Commercialism of Christian Science. That the "Almighty Dollar" holds a still higher post of worship in the Christian Science cult than it is popularly supposed to hold in the religion of the day is shown by the following story, which we quote from the *Public Health Journal* for December: "Some two years ago I was attacked by an affection of the eye (a detachment

of the retina), an ailment I believe incurable by medical science," says a contributor to *London Truth*. "I was persuaded to consult the Christian Scientists, which, out of curiosity, I consented to do. I wrote to Mrs. Ward, then, I believe, 'chief prophetess' in the sect in London. I wrote to her, making the following offer: 'That in the event of a successful treatment she should receive £200 as remuneration for her services; in the event of a non-successful treatment the nominal fee of 2s. 6d.' In answer she wrote that Christian Science did not labor for money, and declined my offer. I wrote again, saying I would be prepared to give this sum (£200) to any charity she might name, she retaining only such remuneration as she thought fit. In answer she replied she 'preferred a guinea a week.'"

The inane folly of this cult is not so distressing as its dishonorable and unblushing hypocrisy. We can respect honest differences of opinion even though they may appear in the light of knowledge puerile and hopelessly ignorant. A kindly feeling of sympathetic pity is the one evoked by such a condition. Even the open roguery of the common charlatan can be met with some respect because it is open. But the hypocrisy of the professional Christian Science healer can provoke nothing but loathing and disgust.

The Treatment of Lupus by Thyroid Colloid.—Dr. Raymond Crawford (*Therapeutic Gazette*, December) reports that at a recent meeting of the Clinical Society of London Mr. Pearce Gould showed a case of lupus of the whole face treated by thyroid colloid with the most striking results. In three weeks from commencing the treatment the whole ulcerated surface had completely healed, and the scar tissue was undergoing transformation from a hard hidebound state into a soft pliable condition. Incidentally Dr. Pringle alluded to a series of cases treated by thyroid colloid; he was of opinion that the thyroid colloid was by far the most efficacious preparation of the thyroid gland that is now used medicinally. He was able to point to remarkable results in a considerable number of cases, but his experience of the after history led him to believe that the cure was seldom if ever permanent, as foci of lupoid tissue always remained behind to light up the disease afresh. It was not made quite clear whether Pearce Gould's was a true case of lupus granuloma, or whether it belonged rather to the category of serofuloderma. Dermatologists seem to agree that the thyroid colloid, like the serum preparations, is much more efficacious in cases of serofuloderma than in cases of true lupus granuloma.

Sterilization of Drinking Water.—Schmubare (*Riforma medica*, November 1898) recommends to each quart of water the addition of three drops of the following solution:

- ℞ Bromine 300 grains
Bromide of potassium 500 "
Water 1,500 minims

After five minutes, neutralize with an equal quantity of solution of monogenic soda ash. A limpid, tasteless liquid is thus obtained. When the water is very impure and strongly colored, a pinch of the bromine solution is added at a time to impart a yellowish color, which permits the impurities to settle.

The Treatment of Pneumonia with Salicylic Acid.—Baker (*Chirurgist*, November 1898) has treated 100 cases of salicylic acid in the treatment of pneumonia. Thus

drug, according to him, loosens the fibrinous coagulum and causes the expectoration to lose its viscosity. He considers it a true abortive of pneumonia. To children, one grain and a half may be given every hour or every two hours. To adults, seven grains and a half every two or three hours. It is to be dissolved in a small quantity of hot sugar water, milk, or chocolate. It is contraindicated in cardiac affections and where there is collapse.

The Diagnosis of Streptococcus Pneumonia.—Lewin (*Bohnitsch. Gas. Bohemia*, No. 16, 1898; *Clinica moderna*, November 23d) arrives at the conclusion, from a study of three cases, that in the streptococcus form of pneumonia the temperature maintains a more or less intermittent character, with rigors and sweating at the beginning of each successive access; the duration of the disease is from one to two months, and the bacteriological examination of the sputum, as of the splenic juice, obtained by aspiration of the spleen, shows streptococci only. In all other respects the clinical picture of this form of pneumonia is exactly like that of the bronchopneumonia of diplococcus.

Faradism in Dilatation of the Os Uteri.—Dr. Jeanne W. Martine (*Journal of Electrotherapeutics*, December) describes a dilator, similar to Nott's dilator, which is connected with one pole of a faradaic battery by one terminal, and by another with a large pad which is placed on the abdomen. The anæsthetic effects of the fine wire faradaic coil are, according to the author, of material assistance.

Dr. Martine says:

"I have used this instrument in a variety of cases. I wish to mention one class where the physician does not, as a rule, consider division necessary. I mean in subinvolution complicated with endometritis: here division causes, first, drainage. Secondly, it acts as massage and sets up a better circulation. The electricity helps us here by its stimulating properties more than its anæsthetic effects, as the uterus is rarely sensitive in subinvolution. My electrical dilator is one of my best friends in nearly all cases of uterine disease, and it can of course be used with the galvanic as well as faradaic currents, and I have yet to see a case so sensitive that I could not dilate by its judicious use. It is indeed simply wonderful how the long, fine wire coil of an Englemann faradaic battery will numb the parts so that little or no distress is felt. I, however, give myself plenty of time in treating sensitive subjects and only do very little at each treatment. One important point I wish to mention: The anæsthetic effect of electricity, faradism at least, is only felt while the current is turned on, and this is the objection to using graduated sounds, much pain being caused by withdrawing, turning off current, and reintroducing a larger size. Theoretically why this is the case I can not say; practically I know it to be so; but the instrument I have described allows current to flow while we are dilating and overcomes that difficulty."

This procedure might be worth a trial in stricture of the urethra, though the catalytic properties of the faradaic current are slight as compared with those of galvanism.

A New Behring Patent. According to the Berlin correspondent of the *British Medical Journal* for December 17th, Prof. or Behring and a Dr. Ruppel have applied for a German patent for a tuberculosis serum.

His application alleges "a method for producing a highly poisonous and immunifying substance from tubercle bacilli or from cultures of tubercle bacilli."

Lawyers' Fees and Doctors' Fees.—The *Medical News* for December 24th in an editorial comments on the case of a distinguished New York lawyer who had received a \$5,000 fee and forgotten all about it, as follows:

No one, we are sure, has the slightest doubt that the distinguished lawyer who denied absolutely having received the aforesaid fee, though it was afterward clearly proved that he had received it, was eminently sincere in his denial. It would simply seem that \$5,000 fees are such common occurrences in a great lawyer's everyday life that he can not reasonably be expected to recall their receipt with absolute assurance if any considerable time has elapsed since the event, or if he happens to have been at the moment of its presentation so busy with other or more important matters as not to have made an act of reflex consciousness and so impressed the trifle on his memory.

But why is it, then, that when the question of doctors' fees gets into court lawyers always insist on their excessiveness? One might think that the generous fees they collect themselves would make them realize that the value of the work of a liberal profession can not be estimated by any cut and dried rules of trade, or commercial deductions as to the value of time. The value of a service in law depends upon the worth of it to the party for whom it is performed, and the following out of exactly the same steps of legal procedure has a very variable fee for its reward according to the circumstances of the client for whom it is done. Why the same rule should not hold for the services of a physician does not seem very clear. But the attempt to put such a principle into action by the doctor brings down upon him, in case of legal complications, the malediction of judge and lawyer, and almost inevitably leads to the extremely unpleasant predicament of having to accept a fee made more or less arbitrarily smaller by the court. We humbly submit that all this seems scarcely in accordance with the American spirit of fairness or with the high principles of equity our legal brethren laud so justly. Let us hope that this little public reminder that "there are others" will give them a fellow feeling that will make them wondrous kind to the little seeming exaggerations that their brothers of the healing art may commit in the making out of bills.

A Tropical School of Medicine in London.—Our usually accurate contemporary, the *Philadelphia Medical Journal*, in its issue for December 24th has a paragraph with this heading. London, we are informed, is a pretty "hot" place—in fact, quite "sultry" in some respects; but for all that it is some degrees north of the tropic of Cancer. A School of Tropical Medicine is, however, what we believe our contemporary to mean.

The Chair of Surgery in the University of California.—We learn from the *Philadelphia Medical Journal* for December 24th that Dr. T. W. Huntington, of Sacramento, has been elected assistant professor of surgery in the University of California. Dr. Huntington is well known throughout northern California as an able surgeon, having been for years in charge of the Southern Pacific Railway Company's base hospital at Sacramento, and the appointment will no doubt be a very popular one.

as we can remember, with apologies to the unknown author whose name we are unable to furnish, and to the periodical (if any) in which it made its first appearance. The song runs as follows:

Ours is a wise and wondrous age, an age of thought and science, sir;

To error, ignorance, and bliss, we've fairly bid defiance, sir;

"Professors" everywhere abound, both in and out of colleges,

And all agog to cram our nob's with "isms" and with "ologies."

With a bow, wow, wow.

Ri tol the riddle, fol the riddle, bow, wow, wow.

Philosophy, as you're aware, material and mental, sir, At one extreme is "positive," at t'other "transcendental," sir;

And each of us who nowadays would speculate *en règle*, If he can't run the rig with Comte must take the tips from Hegel,

With a bow, wow, wow, etc.

We can't assume, so Comte affirms, a first or final cause, sir;

Phenomena are all we know, their order, and their laws, sir;

While Hegel's modest formula, a single line to sum in, Is nothing is, and nothing's not, but everything's becomin',

With a bow, wow, wow, etc.

Development is all the go, of course, with Herbert Spencer,

Who cares a little more than Comte about the why and whence, sir;

Appearances, he seems to think, do not exhaust totality, But indicate that underneath there's some "unknown reality,"

With a bow, wow, wow, etc.

Then Darwin, too, who leads the throng *in vulgum roces spargere*,

Maintains humanity is nought except a big menagerie, The progeny of tailless apes, sharp-eared and puggy-nosed, sir,

Who nightly climbed their "family trees" and on the tops reposed, sir,

With a bow, wow, wow, etc.

Imaginative sparks, you know, electric currents kindle, sir,

On Alpine heights, or at Belfast, within the brain of Tyndall, sir;

His late address some people hold was flowery, vague, and vapory,

And represents the "classic nude" when stripped of all its Drapery,

With a bow, wow, wow, etc.

Professor Huxley has essayed to bridge across the chasm, sir,

"Twixt matter dead and matter quick by means of protoplasm, sir;

And to his doctrine now subjoins this further "grand attraction,"

That con con in man and brute is simply reflex action,

With a bow, wow, wow, etc.

George Henry Lewes, I'm informed, has gone off quite hysterical

About that feeble, foolish thing, the theory metempsychical;

And only finds relief, 'tis said, from nervous throes and spasms, sir,

By banging straight at Huxley's head a brace of brand-new "plasmis," sir,

With a bow, wow, wow, etc.

Then Stanley Jevons will insist, in language quite emphatical,

The proper way to treat *all* things is purely mathematical,

Since we as individual men, communities and nations, sir,

Are clearly angles, lines, and squares, eubes, circles, and equations, sir,

With a bow, wow, wow, etc.

Such are the philosophic views I've ventured now to versify

And, if I may invent the term, in some degree to tersify. Among them all, I'm bold to say, fair room for choice you'll find, sir,

And if you don't, why, then you won't, and I for one shan't mind, sir,

With a bow, wow, wow,

Ri tol the riddle, fol the riddle, bow, wow, wow!

Abortefacient Nostrums.—The recent attempt to blackmail women in England for purchasing advertised abortefacient nostrums has set our energetic contemporary the *Lancet* at work on another investigation commission. The issue for December 17th contains the details of its "critical and analytical inquiry" into two of these nostrums. In the first, savine appeared to be the active constituent of the pills, while in the second case the results of the examination suggested that the liquid was senna and rue tea.

The letters from the *Lancet* to purchase the nostrums were so written as to leave no possible doubt in the reader's mind that the purpose for which the purchase was being made was the induction of abortion. The *Lancet* says: "If any one should find in our conduct here matter for unfavorable comment on the ground that we have tempted Mr. Thomas Ottey to sin, we have to say that we found in him so willing an accomplice that we can hardly have been his seducers, and, secondly, that it is useless to fight a certain sort of stink with rose water."

Professor Stricker's Successor.—According to the *International Medical Magazine* for December, Philip Knoll, professor of experimental pathology at the German University of Prague, is to succeed to the chair of experimental pathology in the University of Vienna, made vacant by the death of Professor Stricker.

The Queen of Portugal and the Study of Medicine.—In our issue for December 3d we quoted from the *Woman's Medical Journal* a paragraph to the effect that Queen Amelia of Portugal had recently graduated as a doctor, and that her first patient was her husband, King Charles I, whom she was treating for obesity. We now learn from the *Medical News* for December 24th that the *British Medical Journal* cries *peccavi* to the indictment of having been the originator, no doubt inadvertently, of this statement, which has been officially contradicted by the Lord High Chamberlain of Portugal.

Original Communications.

SOME CASES TREATED BY
HYPNOTISM AND SUGGESTION.*

By R. OSGOOD MASON, M.D.

IN all investigations claiming to be scientific in character, it is just and necessary to see to it that the facts from which conclusions are drawn are solid. Hypnotism from a scientific standpoint, and in its relation to the medical profession, is still on trial, not as regards its reality; that is conceded. Something which we agree to call hypnotism produces effects. But questions remain regarding its nature and its uses.

I do not for a moment indulge the fancy that I shall be able to answer these questions to your satisfaction, or my own, this evening, nor is that my present purpose. Years may elapse before that desirable end can be reached; but it is only by carefully considering the facts as they are observed and reported that an approximation to a solution of these problems may be made.

To work effectively, the problems must be clearly in mind, and the relation of the facts made evident. For example, concerning the nature of hypnotism, these questions are not yet settled beyond controversy:

1. Is any special influence or effluence passing from the operator to the subject concerned in any of the phenomena of hypnotism?
2. Is the mind or will of the operator an element to be reckoned with?
3. Is the whole matter subjective, pertaining to the patient alone?

Of course, I am aware that by many acknowledged representatives of science the first of these questions is thrown out of court. The second is scarcely in better condition; while the third is received and put forward as the explanation of what is accepted as hypnotism.

Braid and Carpenter, Bernheim and Heidenhain are names to be considered and respected; and they answer the first and second of these questions emphatically in the negative; while Elliotson, Esdaile, Gurney, Richet, and a host of good observers have witnessed phenomena which led them to answer the same questions in the affirmative.

So it seems the part of wisdom to keep the court open and see if new evidence appears.

Then, again, regarding the uses of hypnotism, conclusions are widely different—some considering it not only of very little if any use, but in general absolutely harmful; while others find it not only harmless, but of very marked and far-reaching value. It is evident that some of these conclusions are erroneous, and must have been drawn from a small field of observation—probably only personal—disregarding for the most part the ob-

servations of others, a course which certainly is not always wise; for it must be remembered that the phenomena connected with hypnotism are singularly varied in character. One observer may have witnessed but few of these, or one operator might succeed admirably in the use of hypnotism as a therapeutic agent and not be able to exhibit tricky and unusual phenomena; and any one who has not studied carefully many varieties of phenomena, and with many different subjects, is illy qualified to decide offhand that an alleged phenomenon is not a fact or is not possible. Science is perfectly right to be discriminating in regard to the reported facts and phenomena which are new and unusual; but it may not be wise to reject facts altogether, simply because they do not fall within certain prescribed lines usually known as the laws of Nature, for these laws are variable according to our knowledge of Nature. They are simply the formulæ by which the behavior of Nature is expressed, so far as we know that behavior at the present time, and no further. Yesterday we declared that light could not pass through an inch-thick wooden plank; to-day the interior of a box constructed of such material is illuminated and a coin inclosed in it is photographed.

This is only a modern instance, and is perhaps of minor import; but it is one of a series of surprises from Copernicus to the magician of Menlo Park, which, after a year or a generation, as the case might be, have forced men to revise their formulas of Nature's action in the physical world.

Within the last quarter of a century the attention of all classes of persons has more than ever before been directed to unusual psychic phenomena; and different classes of observers view them from different standpoints and in different lights. One class at once refers the unexplained and mysterious to the supernatural; another class, having scientific tastes and tendencies, at once sets about finding a way of referring them to natural causes, of seeing in them only links in one unbroken chain of antecedents and consequences; but even here, in a field of which we actually know so little, we attempt to bind Nature with laws of our own making, and perhaps reject valuable facts, or hesitate to receive them, because they seem to contradict or contravene some conventional formula which is taken for Nature's ultimatum regarding psychic action.

It is not the acceptance of any particular psychic phenomenon, nor any particular phase of psychic investigation, that I would favorably discuss, but simply a judicial attitude, an open mind, and wide view of a field of investigation which we, as representatives of at least one department of science, and as practical physicians, may find it important to cultivate.

The cases treated by hypnotism and suggestion which I have to report this evening may be conveniently arranged in four classes:

1. Those of a purely psychical character

* Read before the Section in Neurology and Psychiatry of the New York Academy of Medicine, October 28, 1898.

2. Cases illustrating the effect of suggestion on physiological processes.

3. The treatment of physical ailments.

4. The educational uses of hypnotism.

CASE I.—Mrs. C., forty-one years of age, married. Disease: Melancholia, with dominant idea of absolute general inability. She can not walk a block without entire failure of strength; can not read ten lines without feeling that the brain is giving out. For the same reason she can not visit, attend church, nor go to any place of amusement. Sleep is disturbed and unrefreshing. She is generally indifferent, helpless, and despondent. She has already been an inmate of a sanitarium. She came here from a large Western town to consult an eminent specialist in nervous diseases; no organic disease was discovered, and she was kindly referred to me. She came under my care October 10, 1896. I was able to secure a quiet subjective condition between sleeping and waking, but without loss of consciousness. She heard the suggestions in an imperfect, indifferent way, as if at a great distance. Suggestions were as follows: You have no organic disease; there is no reason why you should not be a perfectly well woman. You will *become* perfectly well.

First of all, your appetite and digestion will improve; your sleep will be undisturbed, quiet, and refreshing. All this cloud of discouragement and despondency which is hanging over you will be lifted from your mind and will disappear; you will see things in a new light—bright and cheerful—and you will be greatly encouraged.

These suggestions were repeated quietly, but firmly and confidently, four or five times, with intervals of silence, the whole treatment occupying about half an hour. She was directed to return in two days. The report of her attendant on her return was that there was an entire change in the condition of her mind. She slept well, was cheerful, interested, and hopeful. The same suggestions were given, with the addition that she would be able to walk without fatigue and begin to read with ease and enjoyment.

Between October 10th and October 30th she received six treatments, each report showing marked improvement in her condition, both physical and mental; so that on the latter date she reported herself, and was reported by her attendant—a sister who was accustomed to see her in health—as entirely well. I directed that she should go about and enjoy herself, remain away from me two weeks, and then return. She did so, and on November 14th reported that she was perfectly well; and she remarked, "No one knows how wretched I was five weeks ago, and so no one but myself can appreciate how great is the change."

Two days later she started for her home in the West, where she took her proper place in her family. I have heard several times since that there has been no relapse and that she remains well.

A form of what is usually a purely psychic disturbance is that which relates to the different overwhelming fears or *phobias*—the mis-named hydrophobia excepted.

One of the most common and at the same time most distressing of these is the excessive and uncontrollable fear of thunder and lightning, which may be properly named tonitruophobia. I have observed several instances

of the excellent effect of suggestion in removing this condition. I will relate a single one:

CASE II.—The daughter of a medical friend with whom I was spending some time in the summer was about eighteen years of age and in perfect health. She was greatly afflicted, however, by this unconquerable fear of thunder and lightning—so much so as at times to deprive her of all presence of mind or power of action; and the nervous shock was quite serious in its effects.

On the approach of a thunderstorm she immediately shut herself up in the closest and darkest available place, and remained there until the disturbing influence had passed by. She was an excellent hypnotic subject, and being put in the deep sleep, I suggested that thunder and lightning were usually perfectly harmless; that she had nothing to fear from them, and that now, hereafter, all her dread and terror of them would entirely disappear. She would have no dread, no terror, and no nervous shock, but her mind would be calm and composed, and she would have perfect self-control.

This was repeated with positive assurance several times, and then she was awakened.

The test of the treatment soon came in the form of a terrific country thunderstorm—trying even to the strongest nerves. This young lady, instead of seeking her accustomed seclusion, seemed perfectly fearless, and busied herself with soothing and encouraging the younger children and servants. She was entirely composed and acted with perfect self-control.

Under this same heading of psychic disturbances might be mentioned cases of lifelong and very troublesome somnambulism, and also of night terror in young children, which have been permanently dismissed by a single treatment by suggestion.

The second class of cases to which I would call your attention illustrates the effect of hypnotism and suggestion upon *physiological processes*. By this is meant such processes as digestion, assimilation, absorption, the circulation of the blood, the menstrual function, and lactation. I will refer to a case where the function of the lower bowel was influenced by suggestion.

CASE III.—Miss A. was a bright, intelligent German girl twenty-six years of age, free from any hysterical or nervous symptoms. She was the subject of obstinate constipation; her movements seldom occurred without medicine, and she often went for four or five days without relief. She was easily hypnotized, and one evening, while in the hypnotic condition, she was given a teaspoonful of pure water with the suggestion that it was a bitter dose, but very powerful and would give a very free movement from the bowels at seven o'clock the following morning. She took the water with many grimaces at its bitter taste, and the suggestion was realized with great promptness and energy at exactly seven o'clock in the morning. I could give equally striking examples of the prompt effect of suggestion upon the menstrual function, and upon lactation. I will give an instance of its effect upon the vasomotor system.

CASE IV.—Miss B., forty-two years of age, though in appearance not over thirty, has a ruddy complexion, a bright, intelligent face, and is a teacher by occupation.

She was afflicted with inordinate and excessive blush-

ing. It occurred mostly in company, and especially when addressed by men; then the excessive flush came to her face so as to attract the attention of every one near her. But the most distressing symptom was the mental confusion which accompanied it. The brain seemed to be overwhelmed at the same time: she became dazed, her presence of mind entirely forsook her, she could command neither thought nor word, and was utterly unable to reply. This, of course, often made her appear ridiculous and caused her intense mortification.

She came to me March 30, 1898. A fairly subjective and suggestive condition was secured, with even light sleep. I suggested: You will lose your excessive self-consciousness in the presence of men; you will be calm and confident when addressed by them. The nervous system, and especially the vasomotor system, will act normally; the flow of blood to the capillaries of the face will be restrained, become normal, and the excessive blushing will cease.

According to appointment, she returned two days later. She was greatly impressed with the effect of her treatment; the blushing and confusion were decidedly diminished; the improvement was so marked that there was no mistaking it.

I now learned the following facts: She had two sisters, both of whom have the same trouble and manifested under similar circumstances; also a niece, the daughter of her brother, a girl ten years of age. She herself also had the trouble when a little girl, and even then it was in the presence of boys, as later it was in the presence of men. It was entirely without any sexual ideas or emotion. She spoke with perfect frankness; said that she had been a boy and man hater, avoiding and even insulting them. As she expressed it, she never had any womanly feeling toward men until she was twenty-seven years of age, when there was a decided change in that respect. Since then she had seemed to be attractive to men, had many admirers, and a love affair which had an unhappy ending; but through all these experiences the blushing and confusion remained the same.

I suggested as follows: The old thought of mental confusion, associated with your blushing, even from childhood, will now be removed and dismissed from your mind. It will no longer affect your thought or life. You will be able to converse with men without embarrassment or constraint. Other suggestions made were similar to those at her former treatment.

A third treatment was given April 7th, at which time she reported *very marked* improvement, both as regards blushing and the power of self-control. So great was the improvement as to be a surprise both to herself and her friends.

As she had to leave the city, I instructed her in regard to auto-suggestion while going to sleep at night, and furnished her a formula similar to that I had used.

A month ago I received a letter from her from a distant city expressing great satisfaction at her improved condition. She had also been able to use auto-suggestion successfully, and felt that if there was an return of the trouble she had the remedy in her own hands.

In this connection, at the suggestion of your chairman, I will refer to an incident which occurred thirteen years ago. It was in relation to a case of traumatic neuritis of thirty-five years' duration, and which terminated fatally by exhaustion when the patient was only thirty-eight years of age. Every known remedy was made use of, including repeated section of the nerves

involved, as advised by the most eminent neurologists and surgeons both here and in Europe.

For the last seven years of her life the patient was under the care of Dr. Mary Putnam Jacobi, with the exception of three months and a half immediately preceding her death, when Dr. Jacobi was away.

The case was fully reported in the *American Journal of the Medical Sciences* for July, 1885. I will designate it as—

CASE V.—This patient, Miss T., came under my care June 9, 1885. The affected right hand and arm were of a dark-purplish color, cold, disagreeable to the touch, and entirely useless. The muscles were atrophied and the fingers contracted. They had been in this condition for years. About three weeks before her death I was one day speaking to her about hypnotism, and suggested a trial as a relief, temporary at least, to some of her sufferings. She assented, and by monotonous passes from head to feet, as she was lying in bed, she was put into the condition of light sleep, with easily induced rigidity of a finger or the hand. After ten or fifteen minutes of sleep I noticed that the affected hand had become normal in color. I took hold of it and laid it palm down upon the counterpane. The fingers were easily straightened out, and they retained their extended position. I placed the hand in a comfortable position and made a few passes from the shoulder to the tips of the fingers.

No suggestions of any kind were made. The period of suggestion had not then arrived. Bernheim's book did not appear even in France until the following year, and in English not till three years later.

I allowed my patient to sleep quietly for an hour, and then awoke her. Her hand still remained extended upon the counterpane—a really beautiful object, most delicately white, but still lifelike, a wonderful contrast to the dead thing it seemed before she went to sleep.

Presently I called her attention to her hand, which she gazed at with the greatest astonishment and pleasure.

She awoke with a general feeling of well-being and comfort, quite unusual to her, and it continued several hours; but at length the old conditions gradually returned, and with them the purple color and ungraceful contraction of the hand.

The treatment was repeated on two other occasions with the same result. After the second treatment, looking at her hand with a pleased and humorous expression, she exclaimed: "Well! well! When I go to my next ball I shall surely want you to come and beautify my hand." This incident was not mentioned in the printed report, but it seems to me a fair example of the effect of hypnotism *alone* upon physiological processes.

As an illustration of my third division, the effect of hypnotism and suggestion upon *pathological conditions*, I will present the following:

CASE VI.—Mrs. A., aged twenty-eight years, married; confined with her third child October 23, 1897. Two weeks previous to her confinement the two children which she then had were down with measles. She lived in an apartment, front and back rooms with two bedrooms between. Sanitation and disinfection were attended to as well as possible under the circumstances. Confinement was normal, and everything went fairly well until the fifth day, when I found her with a temperature of 103° F., excessive headache, flushed face, mental confusion, no sleep for twenty-four hours past;

pulse 116, hard, and irregular. There was great pain in the back and limbs, and the whole was accompanied by an overwhelming feeling of apprehension.

No milk had appeared and there was no fullness of the breasts. She had never been hypnotized, and I had never spoken to her of hypnotism, nor did I now, but her condition was so pitiable that as I stood by her bed I placed my hand soothingly upon her forehead, then made light passes over it with gentle touches; in four or five minutes her eyelids quivered and closed, and presently she was asleep. Passes made over an outstretched finger made it rigid. Undoubtedly she was in the deep hypnotic sleep. I then made passes away from her head and down her body, from head to feet, for ten minutes, then allowed her to sleep fifteen minutes; suggested that her headache and all her pains would at once disappear, her mind become clear, and that she would have abundant sleep; I then suggested that she would awake feeling greatly refreshed when I counted five. She awoke promptly as suggested, and was perfectly free from pain; her temperature had fallen a degree and a half, and all her confusion and apprehension had disappeared. She slept most of the afternoon and night. The next day I thoroughly washed out the uterus with a one-per-cent. solution of lysol and left her comfortable. The following day, when I called, she was still comfortable, but complained bitterly that she tasted the wash I had used all the time, that it was intensely disagreeable, and even nauseating. I hypnotized her very quickly and suggested that she would awake quite free from the taste or any disagreeable effect of the lysol. On awakening her, every trace of the objectionable taste had disappeared. She made a slow but perfect recovery.

CASE VII.—C. L., actor, forty-two years old, was brought to me April 30, 1898, for treatment for both the alcohol and morphine habit. He had recently been taking his quart or more of whisky and ten to fifteen grains of morphine daily. Within the past few days he had left off about half of each drug, and was in very bad shape, though still able to be about. He could take no breakfast, and very little food of any kind; suffered severe pains in his legs and back; was bathed in cold perspiration, was weak and depressed, hardly hoping to be cured.

Hypnotized, and found him an excellent subject. Suggested a very little decrease in his drugs, but assured him of final success; also that his pains would be greatly relieved, that he would sleep at night straight on until seven o'clock in the morning, that he would awake refreshed and eat a good breakfast, would feel stronger, and come to me for treatment the following day. These suggestions were almost exactly fulfilled. He had slept, taken food, and retained it perfectly.

I then suggested that he should reduce his whisky to four fair drinks a day, and his morphine to three grains; and I directed carefully how each should be taken; other suggestions similar to those the day before. These suggestions were also carried out almost to the letter without his knowing what they were. Asking him why he did it, he said he did not know, only he felt that he *could*, and that it was *best*.

During the next four days the whisky was diminished and dropped entirely.

I then commenced reducing the morphine entirely by suggestion, still allowing him to use the syringe himself, reporting to me every second day. When reduced to one grain a day, I gave him the morphine that he was to

use each day in solution, assuring him that he would soon be safely free from his bondage without the least suffering.

At the end of six days he had for *three days* been taking only pure water made slightly bitter with strychnine. He had a great dread of the sudden removal of the morphine, and when informed that he was now entirely free from his relentless enemy, and had not even had a particle of morphine in his possession for three days, he nearly fainted with surprise and delight.

The whole treatment lasted six weeks.

During the last half of the time, in addition to suggestion regarding his disease, I was also suggesting ambition and higher ideals regarding his profession and his own position in it, that he was capable of better things, and would rise to the attainment of them. To-day he is playing here in this city in a first-rate company, and in a much higher grade of dramatic work than that in which he had formerly been engaged.

Regarding my fourth division—the educational uses of hypnotism—I would say that an article was published in *Pediatrics* for February, 1897, in which a series of cases was given, illustrating these uses, in both intellectual and moral education. Reprints of the article have been made, which some of you have probably received, and I should be pleased to send them to any or all who desire it and will send me their names and addresses. I will add a single example here.

CASE VIII.—M. V., a boy nine years of age. Father a criminal with a State-prison record. Mother an upright, mild, intelligent woman. The boy has a bad face when in repose, but better when animated or smiling. His head was markedly unsymmetrical in infancy and early childhood. Left ear deformed. Sense of right and wrong decidedly dull; intellect good. He was disobedient, rough, uncouth; coarse in speech, violent in temper, and regardless of consequences when angry; cruel to playmates, pulling their hair, pinching and striking them. His mother and grandmother, with whom he lived, could do nothing with him, nor could any one else; and seeing these characteristics, his mother became most anxious concerning his future. I attempted to hypnotize him at my office more than a year ago, but he was violent and noisy in his resistance, and it was impossible to secure his attention. For a whole year afterward he would not come into my house, but always ran away as soon as he was brought to the door. At last, three months ago, things became so bad, he was so perfectly unmanageable, and his temper so outrageous, that his mother begged me to come to the house and see if I could do anything with him.

Having secured *carte blanche* for whatever course I chose to pursue with him, I went. He was in the back room, his grandmother urging him forward toward the front, he kicking and resisting. Without speaking, I went directly to him, seized him firmly by one wrist, and brought him topsy-turvy through two intervening rooms, gave him a thorough shaking, and sat him down violently in a chair. He smoothed down his bang, whimpered a little, and gruffly remarked that I had ruffled his hair. I told him I had not intended to disturb his hair, but as he had never obeyed anybody I had come to the house for the express purpose of making him obey me, and I should most certainly do it. After a few moments I said, quietly, "Now go and lie

down on the bed in the next room." He started, walking toward the bed, but when near it he set off on a full run past it and into the back room. I brought him back in no gentle manner, and again ordered him to lie down on the bed. He went toward it as if to obey, but suddenly sprang under it, and clung to the slats underneath with hands and feet and hung there like a monkey. I turned up the mattress, dislodged him by main force, pulled him out, gave him a lively spanking, and surprised him by tossing him vigorously upon the bed, with the command to lie there quietly until I gave him permission to move. He obeyed. Presently I ordered him to go into the front room and sit down again in the chair he had before occupied. Again he quietly obeyed. I said: "All right; now you understand you will obey me. I don't want to hurt you. I want to be a good friend to you, only you must obey me."

I then in a pleasant way gave him a short lesson, picturing to him very plainly the course of a boy such as he was, and where it would be likely to end; and also showing what he might be if he would change his course. I told him I should be at the house again in a day or two and I should expect him to meet me pleasantly, shake hands with me, and do whatever I directed him.

The next day there came a telephone message begging me to come up, M. was outrageous again. I went. He was backward in greeting me, but at length came and shook hands. I afterward learned that there had not been the slightest improvement in his behavior, and the cause of his mother's sending for me was his outrageous conduct at the table, when, in a fit of anger, he had thrown a plate at his grandmother. I talked to him pleasantly a moment, and then said very quietly, "Now go and lie down on the bed." He did so at once. I sat down beside him, and taking his two thumbs firmly in my hands I said: "Now, M., I want you to look steadily at that little stud in my shirt-front; keep your eyes very steadily fixed upon it." He did so, and I never secured better or more concentrated attention from any patient.

In five or six minutes his eyelids quivered and soon drooped. I closed them, suggesting sleep; and directly he was in the sound hypnotic sleep. I then presented the two pictures again, the bad course and the good course, and suggested that they would always be present, distinct in his mind, that he would dislike the *wrong* course and desire to avoid it, and choose the *good* one. I suggested definitely that he would be kind and considerate of his mother, and obey her as well as me. I repeated these suggestions very positively, let him sleep ten minutes, and repeated them again, and then awoke him by counting.

The effect of this treatment was very marked, his whole manner at home was changed, and he became comparatively docile and manageable.

He came to my office for his next treatment, which was perfectly successful. I have given him in all six treatments, and the improvement has been maintained and increased. He is not yet by any means perfect, but his general behavior is changed, and I am sure that such definite improvements in his conduct, and in making such pictures upon his mind, as I think will help to develop his better nature and qualities. He is a lover of flowers, and on two occasions has brought some of his own choosing to me. He has lost none of his shyness; he is full of life; is mischievous, playful, and even upon his mother; but he is affectionate and generally obedient, though the strap is occasionally exhib-

ited as a reminder. His will is not broken, but he has self-control, and he is far more considerate of others than formerly. In short, he is a fair example of one of the educational uses of hypnotism and suggestion.

I have to apologize for detaining you with the description of my first serious interview with this boy, but I wished to show you just what sort of a case I had to deal with. It was necessary to secure obedience before I could secure attention, and attention is necessary in most cases in order to secure the proper subjective conditions.

If this imperfect description of a few cases which have come under my own observation has served to render more definite your views concerning the varied uses of hypnotism and suggestion, and to increase your respect for a greatly misunderstood but in clean and competent hands most effective and elevating agent, my desire will have been fulfilled.

PRACTICAL POINTS IN PERCENTAGE FEEDING.*

By WILLIAM L. BANER, M. D.

At a recent session meeting of the academy a well-known pædiatrist ventured the opinion that it would be a decade before percentage feeding was generally adopted by the profession. This remark was accompanied by a glowing tribute to the great value which percentage methods had been to himself. While this view of the case seems decidedly pessimistic, there can be no doubt, as was stated in a paper read by me before this society last year, that percentage feeding is not receiving due recognition from the profession in general. This is owing in part to its friends who have burdened the subject with mathematical niceties which complicate without giving increased accuracy; and in part to the general disinclination of physicians to venture into anything which at all savors of mathematics.

In considering this matter, it seems to be forgotten that these are the same old mixtures—except that something definite is known about them. Every percentage mixture produced in the laboratory by design has undoubtedly been previously produced by accident in some tenement kitchen. The gist of percentage feeding is simply the connecting link which it gives between the baby's bottle and the physician's mind. The evident value of the percentage method and the equally evident fact that a large majority of bottle babies would continue for some time to have their bottles filled in the kitchen and not the laboratory, present themselves in my paper on the Home Method of Preparation of a Method for connecting percentage feeding with home nursing.

Several methods had been previously proposed, each based on some particular sort of milk analysis. The

* Read before the Society of the American Academy of Pediatrics, October 13, 1898.

analyses made by different chemists have, of course, shown slight variations, due to the varying personal equations of both chemists and cows. A careful examination of the subject, however, shows that the considerations of these small differences adds absolutely nothing to the accuracy of results, but does materially complicate what should be a simple and easily understood matter. The method proposed in my paper was based upon very simple whole numbers, which a review of the standard analyses showed to be a fair working average. The reception of this paper, which appeared in the *New York Medical Journal*, March 12, 1898, has been very gratifying from the fact that a number of well-known paediatrists in different parts of the country have been kind enough to express their commendation, and from the fact that the equations proposed are being taught to classes in several different medical colleges. A few adherents of more complicated procedures have insisted on the theoretically greater accuracy of using certain fractions. The answer to this criticism is, however, that with far simpler calculation the end results are practically identical with their own. Moreover, among those who insist on fractional niceties, there are, unfortunately, some whose methods actually show very considerable errors in the fundamental principles.

An instance of this has recently appeared in the *Boston Medical and Surgical Journal* for September 22, 1898, in a paper of Dr. J. L. Morse, who is connected with the Harvard Medical School. The method of calculation proposed by Dr. Morse is based on the idea that if a given quantity of milk containing four per cent. of fat is set for six hours all the fat will rise to the top quarter, which will then be ten per cent. cream, the under three quarters being a convenient solution of proteids and sugar, without any fat to disturb the calculation. This is the same mistake made by Dr. Rotch in his *Paediatrics*, and it is the cause of the inaccuracy of his formulæ for home use. This error has been pointed out more than once, and it is unfortunate that it should be again promulgated, as the simplest calculation shows that this under milk actually contains *two per cent.* of fat, and not *two tenths per cent.*, as stated. With an error of two per cent. in the constants added to the usual fractions to confuse the general practitioner, it need not be wondered at if he shies a little at the whole percentage plan.

In the paper read by me last year the requisite amounts of cream, milk, sugar, and water for giving desired percentage mixtures were expressed in equations or working formulæ without explanation of how these formulæ were derived. The very considerable number of inquiries received would indicate that many methods, many fractions, and a few widely disseminated errors have so befuddled this entirely simple subject that some statement of elementary principles would not have been amiss—and this fact must serve as my excuse for doing so now.

In thinking of percentage mixtures it is necessary to have in mind some simple standard of average good cow's milk. An examination of the various recognized analyses shows that the number *four* will fairly represent the percentage of each of the three constituents of milk with which we have to deal. This is not quite exact as regards sugar, which somewhat exceeds four per cent., but it is decidedly easier to allow for this difference when we come to actually put the sugar into the bottle, than to carry fractions through the entire calculation. With unusually rich milk, too, some allowance may perhaps be made for the extra fat; but this is so rare as to scarcely need mentioning.

Milk, then, is water holding in solution or suspension four per cent. of proteids, four per cent. of fat, and a little over four per cent. of sugar. Cream is simply whole milk into which a certain amount of *extra fat* has risen.

Thus, ordinary sixteen-per-cent. gravity cream is whole milk plus twelve per cent. of extra fat, etc., the *extra fat* in any cream being four per cent. less than the total fat content. The general principle upon which percentage mixtures are figured is simply this: As milk and cream contain practically equal proteids, it is the *quantity* introduced into the mixture which establishes the proteid percentage, and the *quality* which establishes the fat. For example, a mixture of one part milk and three parts water gives one per cent. of proteids. One part of sixteen-per-cent. (ordinary skimmed) cream and three parts of water gives also one per cent. of proteids, but in the former mixture there will be one per cent. of fat and in the latter four per cent. By using part milk and part cream and varying the proportions of each it is evident that any intermediate fat percentage can be obtained without changing the one-per-cent. proteids. Knowing that a fourth of any mixture must be milk, or cream, or mixed milk and cream to give one per cent. proteids, it is easy to figure the amount necessary for any percentage by multiplying. Thus, ten ounces of mixed milk and cream and thirty ounces of water will give forty ounces of a mixture containing one per cent. proteids. If we want one and a half per cent. proteids the mixed milk and cream must be raised to fifteen ounces, etc.—that is, we multiply one fourth the total quantity of mixture desired by the desired proteid percentage. Knowing the requisite amount, Shall it be all milk, all cream, or mixed milk and cream? If it is desired to make the proteid and fat percentages equal it is evident that milk alone is necessary. If, as is usually the case, it is desired that the fat shall exceed the proteids, a certain amount of cream must be used, the amount depending on the "extra fat" contained in the cream which happens to be available—for instance, with sixteen per cent. cream for every unit of percentage that we want the fat to exceed the proteids we must use cream to the extent of one twelfth of the entire mixture. Or, stated as a general rule (for any richness of cream),

the amount of cream will be: Quantity of mixture divided by the "extra fat" in the cream to be used, and multiplied by the difference between desired fat and proteid percentages. We now have a mixture of milk, cream, and water having the desired proteid and fat percentages, and having a sugar percentage which is practically the same as the proteid percentage. It is only necessary to add enough dry milk sugar to bring to the desired percentage. For instance, suppose our mixture of milk, cream, and water has been so made as to contain two per cent. of proteids and we want it to contain six per cent. of sugar, we must add four per cent. of dry sugar—that is, we find the necessary amount of sugar by multiplying the total quantity of mixture by the difference between the desired sugar percentage and the desired proteid percentage, and divide by one hundred. We may now use slightly less sugar than the calculation calls for (generally by knocking off small fractions), in order to allow for the fact that milk and cream contain a trifle over four per cent. of sugar.

If these simple principles have not been complicated in the telling, it is evident that pencil and paper are not needed for calculating percentage mixtures with considerable accuracy.

Being called upon to prescribe nourishment for an infant defrauded of its natural supply, and it being desired, for economic or other reasons, to mix the food at home, the question of definite milks comes at once to the fore. The laboratories furnish good clean milk containing four per cent. and creams containing eight, twelve, and higher percentages of fat. These creams are very desirable, but the expense is not inconsiderable, and, in fact, unless some care is exercised, may fully equal that of using the laboratory mixtures. If these creams are not available recourse must generally be had to the ordinary commercial creams or to the creams obtained by letting a bottle of good milk stand for a certain length of time. In this way we can obtain fairly accurate creams of eight, ten, twelve, and sixteen per cent. of fat, depending on the length of time allowed to stand.

If fresh average milk be set in ice water for four hours the top third will be eight per cent. cream. In six hours the top quarter will be ten per cent. cream, while the top fifth will probably average twelve per cent. If milk is set for twelve hours or longer the cream layer will contain sixteen per cent. fat. A very good and, considering its advantages, not expensive procedure is to use in this way the laboratory milk, which is definite four per cent. milk and free from pathogenic bacteria.

In making home mixtures we should always, when possible, use the lowest cream which will give the desired fat percentage. In very many cases the fat and proteid percentages which we desire our mixture to contain will bear the ratio to each other of two to one, two and a half to one, three to one, four to one, etc. Such mixtures can be readily made by simple com-

binations of eight, ten, twelve, or sixteen per cent. cream with water and without using any milk—simply carrying Dr. Meigs's mixture a step further and adapting it to the percentage idea.

It is evident that the calculating of such mixtures is simplicity itself by the principles above stated. If, for instance, we desire sixteen ounces of a mixture containing four per cent. fat and two per cent. proteids the simplest and best way of getting it will be to use eight ounces of eight-per-cent. cream and eight ounces of water, but in case other creams are more available we must remember that we are by no means tied down to the use of eight per cent. cream. We can produce the same formula with mixtures of whole milk and centrifugal cream with water or whole milk and skimmed cream with water, the proportions being quickly calculated. The reason for using the lightest possible cream is simply in order that as little disturbance as possible of the emulsion may take place. It is for this reason that some pediatricists prefer the mixtures made of whole milk, cream, and water to those made by the laboratory method, where under milk is used, necessitating heavier cream. Several physicians have written me that they considered the former mixtures actually to have a higher nutritive value.

If this shall prove to be the case, the laboratories can, of course, be depended upon to make the necessary changes in method. It would be rather hard on them, however, from an economic standpoint, to abandon the use of skimmed milk in their mixtures in a town where it is against the law to sell that useful article. At the present time, however, this entire subject of emulsion disturbance is still in its infancy.

72 WEST FORTY-FIFTH STREET.

THE DIAGNOSIS OF OBSCURE CASES, AND THE TREATMENT OF ALL CASES OF TYPHOID FEVER.*

By JAMES T. WHITTAKER, M.D.

CINCINNATI

REPORTED BY S. MALSHARY

From the history which you have just heard you will have no difficulty in making a diagnosis of typhoid fever in the case of this young woman. Indeed, the physiognomy is so distinctive as to suggest at once the nature of the disease. You may see the dullness and hebetude depicted in the expression, and the general prostration is as evident as the pallor of the face. This is the age of predilection of typhoid fever, just previous to full maturity. There was a feeling of depression, weakness, and discomfort. That is all, of course, but, as this term is too general, the condition is best expressed in the French word *malaise*. There was no sleep for a week or

* A lecture delivered at the Great Samaritan Hospital Clinic, Cincinnati, October 25, 1898.

two, a disinclination to effort or to work; with it all a loss of appetite, headache, confusion of ideas, some pain in the bowels, and diarrhœa. At last the patient was totally incapacitated for work, was unable to be on her feet any longer, and was thus brought to the hospital and put to bed. The examining physician discovered at once that there was fever, the temperature ranging from 100° to 102° F., that there was some slight meteorism, with enlargement of the spleen, and you may yourself see the rose-colored lenticular spots, which were first pointed out by Louis considerably over half a century ago as characteristic of this disease.

So the typhoid state—that is, the smoke about the brain, the continuous fever, the abdominal signs, the enlargement of the spleen, and the eruption, all of which we recognize readily in this case, constitute the typical picture of a typhoid fever.

The majority of cases which you see will show all of these signs if you look for them carefully enough and at the right time. The hebetude and depression of spirits belong among the prodromes, the headache and fever show themselves from the start, the enlargement of the spleen develops in the course of a few days, the abdominal symptoms, including the diarrhœa (constipation as an exception), in the course of the first week, the eruption from the tenth to the fourteenth day disappearing, as a rule, by the beginning of the third week.

But you may readily understand that you might be called to see the case in its earliest stages or days, or in its later history, when some of these signs were absent. Then there are always only too many cases which run an irregular or atypical course. These are the cases which most embarrass the practitioner.

Typhoid fever is oftentimes masked under the picture of a meningitis, pneumonia, tuberculosis, and sepsis. Typhoid fever may itself produce any of these conditions, so that they may be merely symptoms of this disease, and then, as is well known, any disease may assume a so-called typhoid type and thus confuse the diagnosis.

As to malarial disease, which was always formerly the most confusing, there is now much less difficulty in distinguishing this affection.

The most valuable contributions in medicine are those which enable us to earlier diagnosticate a disease. Two such contributions have recently been made to the diagnosis of typhoid fever. One is the so-called diazo reaction and the other the Widal blood test. Either of these test is as valuable as any of those which have been mentioned, and one of them, the blood test, is of more value than any of the rest.

The Diazo Reaction. The diazo reaction is inseparably connected with the name of Ehrlich, who has made so many contributions to the recognition of disease by color tests, and especially to the early diagnosis of tuberculosis. The diazo reaction in it causes a peculiar color which is imparted to the urine by the addition of certain reagents. It is a test of execution, so

simple, and so valuable that it should never be omitted in the study of a case of fever in which there is the least doubt as to the diagnosis. At any distance from a bacteriological laboratory the blood test is impracticable, but the study of the diazo reaction is as easy as the test for albumin in nephritis. It can be made in less than two minutes. The reagents will keep for many months, so that the test is in every way perfectly practicable.

The diazo reaction requires for its execution a small graduated glass which measures three cubic centimetres (a scanty drachm of our measure), an ounce of sodium nitrite (one-half-per-cent. solution), and a preparation of sulphanil acid, which is made as follows: To water, one thousand cubic centimetres, add HCl fifty cubic centimetres, and thereupon sulphanil acid to saturation; finally a bottle of aqua ammonia.

The test is done as follows: To three cubic centimetres of urine add one drop of the sodium-nitrite solution, and shake the glass to incorporate it; thereupon three cubic centimetres of the sulphanil-acid solution, and shake the mixture. Now pour in an excess of ammonia, not drop by drop; shake again. Hereupon a reaction shows itself at once, which, if positive, consists in a rose-red or dark-red color. A negative reaction shows a brownish or yellow color. The reaction is almost instantaneous, and the color is distinctive. You may, if you choose, and it is a wise precaution to take at first, test a specimen of normal urine at the same time that you may have the contrast of color. But if once you see this rose-red hue you will not need to take this precaution again.

I am having carried in now this little boy nine years old who was brought to the hospital ten days ago to be operated upon for appendicitis. When he came to the house he lay upon his back with his leg drawn up, and there was a tumor to be felt in the right iliac fossa. The surgeons did not like to do the operation at his home, on account of the surroundings—a remarkable restraint for surgeons to exercise in facing this diagnosis—so they brought the child here. It did look like a case of appendicitis, but, as the whole abdomen was somewhat tumid, the spleen apparently enlarged—a fact difficult to determine exactly—we concluded to test the urine before going any further. Here is the test. Observe now how the amber-colored urine is transformed to a deep rose-red by the final addition of ammonia. This reaction does not occur in appendicitis. But to make the assurance doubly sure, we also tried the blood test, and got here, too, a positive reaction. The boy is now rapidly recovering from typhoid fever. He would have probably recovered from an operation for appendicitis, and the case would have gone on record as swelling some surgeon's statistics of successful results in the acute stage.

The diazo reaction has now received so much consideration as to have had its value definitely established. Thus Krakiewicz made 16,367 tests in 1,105 different cases, finding the diazo reaction in every case of military tuberculosis. In ordinary pulmonary tuberculosis it

has prognostic as well as diagnostic value, as it is present only in those cases which run a rapidly fatal course. Any complications with nephritis, however, excludes it, as the test is found negative in these cases. In typhoid fever it is apt to be absent in the last stages, but it is found in the first and second stages, even in the mildest cases. A return after disappearance indicates a relapse. The patient can not, therefore, be considered convalescent so long as the diazo reaction shows itself.

The beauty of the diazo reaction consists in the fact that it is nearly always positive in typhoid and typhus fevers. In typhoid fever it is nearly constantly present from the middle of the first week on. You may therefore be misled by making an examination a little too soon. If so, you must repeat it later. The reaction disappears, as a rule, about the time of the first break in the fever—that is, about the twenty-first or twenty-second day. We say that it lasts, as a rule, from the fifth to the twenty-second day, and this is exactly the period when we are called to make the diagnosis in the great majority of cases.

The diazo reaction shows itself, however, also in other diseases. Thus in measles, which it distinguishes in this way from scarlet fever; in tuberculous meningitis, which it distinguishes in this way from the simple form. Now, as a rule, there is not much difficulty in differentiating measles by its coryza, and tubercular meningitis by its long prodromes, bronchial catarrh, intestinal catarrh, lymphadenitis, etc. Then, too, these diseases which might confuse us rarely come into consideration. The rose-red color is absent in simple meningitis and in all kinds of rheumatic affections which might simulate typhoid fever. It is also absent in pneumonia and diphtheria. It is absent also in sepsis, unless the sepsis depends on or is a symptom of typhoid fever. Of this we will speak again.

Unfortunately, the diazo reaction is sometimes absent in typhoid fever, so that while a positive reaction will diagnosticate the disease, a negative reaction will not exclude it. Thus, as before stated, it is absent in the first and the last days of the disease. In some cases it begins to disappear as early as the second week and sometimes as early as the tenth day. Thus, as you see now, we fail to get a typical diazo reaction in this typical case of typhoid fever, which is now at the end of the second or the beginning of the third week. This is, therefore, one of the cases in which the diazo reaction absent itself early in the history of the disease. But it is not impossible that we are further along here than we think.

The diazo reaction is sometimes absent also in typical cases of typhoid fever even when it ought to be present, but such an absence pretty much always indicates a complication. Sometimes after it has disappeared for a time it reappears, and such a reappearance is valuable as indicating a probable relapse of typhoid fever. One point of especial value is that medication has no influence upon it.

I had a man here in the hospital last year who came in with a diagnosis of meningitis. His mind was hazy all the time, he was delirious most of the time, and the disease was protracted far beyond the history of any ordinary typhoid fever—in fact, in the sixth and seventh week. There were no abdominal symptoms, save some dysenteric phenomena; there was no eruption and no enlargement of the spleen. The patient was undergoing a slow marasmus from inanition. The relatives called a consultation with a specialist in neuropathic diseases, Dr. Hoppe, of this city. Under thorough examination of the case he had to admit with me that the diagnosis lay between typhoid fever and meningitis. We now made the diazo-reaction test, and got a perfect reaction, prolonged thus far beyond the natural duration of it. This reaction was the more valuable because the blood test was imperfect. We felt ourselves justified, with this additional corroborative sign, in making a diagnosis of typhoid fever, and the clearing up of all the symptoms in the course of another week seemed to justify this opinion. A tuberculous meningitis would not have disappeared in this way.

The diazo reaction is thus valuable as occurring in the majority of cases of typhoid fever in certain periods in the course of the disease. It is sometimes absent even at this time, and is, I repeat, absent, as a rule, at the beginning and end of the disease. The diazo reaction is not therefore pathognomonic.

What is this diazo reaction? While the exact nature of the reaction is unknown, it is supposed to depend on the decomposition of certain albuminoid bodies, one product of which, chemogen, is considered to be the distinct cause. Now this chemogen also occurs in other diseases, and especially in pulmonary tuberculosis, so that where it is impossible to make this differentiation by other signs of either typhoid fever or tuberculosis, it is necessary to turn to the consideration of another test—to wit, the blood test, the so-called Widal reaction.

The Serum Test.—The attempt to diagnosticate typhoid fever by the disclosure of the typhoid bacillus is difficult and impracticable, if only for the reason that it requires a special bacteriologist to make it. But the Widal reaction demands no particular skill. This reaction consists in the immobilization and agglutination of the typhoid bacilli in a recent culture when brought in contact with the blood of a patient affected with typhoid fever. Widal made his first contribution as long ago as 1896. Antisera in this reaction, which led up to it, had been made several years before, but Widal made the subject thoroughly practicable with the discovery that experiments with dried blood show all the characteristic properties. We make our tests here altogether with dried blood and recent cultures, and Dr. Malbury, who has devoted a good deal of time to this subject, will proceed to make these examinations before you. We take the blood by puncture from the heel of the finger, streak it on a slide with a sterilized water

and then with alcohol, upon a clean glass slide, which it is not necessary to sterilize. A minute amount of the typhoid culture is taken from the test tube and is diluted with a drop of distilled water. This culture is twenty-fours old, which is about the best age. The blood if dry is moistened with a drop of distilled water, and of this mixture a minute fragment of a drop, not enough to cause coloring, is added to a drop of the emulsion or dilution of the typhoid-bacillus culture. The arrest of movement of the tubercle bacilli and the agglutination into clumps become apparent in the course of a few minutes, sometimes earlier, sometimes later. Any agglutination which occurs as late as two hours is accepted as decisive. The rapidity of arrest of movement and agglutination is not determined by the gravity of the diseases, so that the test has value only from a diagnostic standpoint, but it has extreme value in this way, because it is a specific arrest, for, as you might imagine, the arrest of the typhoid bacillus can not be brought about with healthy blood or with the blood of other diseases. Of the two factors, the immobilization is of more value than the agglutination, for agglutination does sometimes occur from other cause. The blood test shows itself early, usually by the end of the first week, and persists throughout the course of the disease, and sometimes for many months and even years afterward. In fact, the condition sometimes persists for life; at least it has been recognized as long as thirty years. This fact interferes to some degree with the value of the test, for it is necessary to know whether the patient will have had typhoid fever in the previous history. On the other hand, a clear history of an attack of typhoid fever almost necessarily excludes a repetition of the disease.

In making the blood test it is necessary to use diluted solutions. Any agglutination or even an immobilization which should take place in a concentrated solution would not necessarily indicate typhoid fever, but a change in a dilution of one to twenty or one to forty is almost pathognomonic.

In our case, as you will see by examining the specimen, the arrest of movement and agglutination are both distinctly pronounced.

Of the two tests the blood test is by far the more valuable; it is, in fact, practised with precision, almost pathognomonic. But the test, for some unknown reason, sometimes fails even in genuine cases of typhoid fever. Eshner has recently recorded a case in which the blood test showed itself distinctly in the relapse, but was wanting in a primary attack. Of course, one may always entertain a doubt whether the attack in which the blood test was absent was really typhoid or some simulating disease. Here we may have the diagnosis cleared up by the use of the other test, the diazo reaction, or in an extremely doubtful case or set of cases, by the discovery of the typhoid bacilli in the stools. Thus one test may correct the faults or substitute the defects of the other.

I have at the present time under treatment a young lady whose symptoms bear the aspect of dysentery. She has tormina and tenesmus with bloody stools. There is a temperature every evening ranging about 100° F. There is no enlargement of the spleen that I can detect and no roseola, though the disease is believed to be at the end of the second week. The diazo reaction is imperfect, but the blood test is positive. This young lady reached home two weeks ago from the East, taking her meals on the train. She was accompanied by a nephew, a boy aged four, whom I had treated for exactly the same symptoms, considering the case to be a dysentery. The boy had about recovered when the young lady was taken ill. I was still inclined to consider the case of the young lady as dysentery, when I heard that a third party, a child on the same train, in previous perfect health, attacked at the same time, was now lying ill with unmistakable symptoms of typhoid fever. Whether one might be willing to make an absolute diagnosis of typhoid fever in the case of the young lady or not, it would at least be necessary to adopt the precautions pertaining to that disease, which would extend over a longer time than the treatment of a simple dysentery. Typhoid fever does begin sometimes as a dysentery.

One is not justified in our day under any circumstances in puncturing the spleen to get the typhoid bacillus, as a fatal accident has already occurred from the rupture initiated by this minute puncture in a spleen rendered so soft and friable as to be almost brought to a pulp by the lesions of typhoid fever.

Stewart got the reaction in 1,000 cases of suspected typhoid fever, using in every case dried blood. The diagnosis had been established clinically 538 times. In 969 cases the Widal reaction corresponded with the clinical results. In three of the thirty-one cases the reaction was positive, while clinically the diagnosis was not made; on the other hand, the reaction failed in twenty-eight cases in which the clinical diagnosis had been established. The reaction failed in ten cases in hospital and twenty-one cases in private practice. The agglutination of the blood was observed five, eight, and in one case ten years after the typhoid fever. W. C. Brown called attention to the difficulty of making the diagnosis in the tropics because of the confusion with malaria, which in this region shows similar symptoms.

The demonstration of the plasmodium by no means indicates that the symptoms present depend upon malarial infection, for the sporozoa of malaria are found often in the blood of patients who feel perfectly well, while but few parasites are detected in those who are gravely ill. Brown used the Widal serum reaction in more than a hundred doubtful cases at Penang. It was only in two cases that the further course of the disease failed to support the serum diagnosis. In all the other cases it was perfect. The serum reaction repeatedly furnished essential service in early diagnosis. Brown ob-

serves that if the drop of serum bouillon, in which agglutination had taken place, was allowed to become dry, and then water was added anew, the heaps dissolve themselves and the bacilli again become mobile. It was seen from this observation that the bacilli do not stick firmly together. An addition now of new serum renders them immobile and again agglutinates the bacilli.

With the use of these two tests we may pretty much control the situation, and there is no longer much room for doubt in a diagnosis of even obscure and irregular cases of typhoid fever. We may now understand certain cases in this way in which the abdominal or local symptoms are insignificant or slight, the cases of so-called "typhoid sepsis."

Typhoid Sepsis.—A good illustration of these atypical cases was furnished in the reports of Chiari and Krauss in the recognition of septicaemia, not of typhoid type, but of typhoid origin. These authors published nineteen cases, which all came to autopsy under Chiari in the Pathological Anatomical Institution at Prague. Of these cases, seventeen had been diagnosticated as typhoid, and two had been shown to be typhoid on autopsy. Of these cases there were four groups. The first two groups showed nine anatomically typical cases and two anatomically atypical cases, both of which were, however, still recognizable. The third group was most important. It included five cases in which it was impossible to demonstrate the exact character of the disease on autopsy, and it was only by the use of the serum test that the clinical diagnosis received its confirmation. The bacteriological investigation showed in all five cases the presence of the typhoid bacilli in different organs, the gall bladder, mesenteric glands, spleen, kidneys, and urine. These cases show that infection with typhoid fever may occur without any definite localization, so that a pure typhoid septicaemia is not infrequent.

There was a case published in connection with these which could be demonstrated as typhoid neither microscopically nor bacteriologically, nevertheless the serum test made in life and on the dead body proved the diagnosis. There had been a number of typhoid affections in the same family.

The fourth group in which the diagnosis of chronic tuberculosis had been made clinically and had been demonstrated upon autopsy, nevertheless gave a positive serum test of typhoid fever. Now, although the bacteriological examination turned out negative in these cases, it was concluded that the patients had suffered from typhoid infection in their previous history.

The later observations which would go to deny the specific importance of the serum test, especially those cases in which bacteriological examinations had been made post-mortem, seemed to be without force. It is recommended in these obscure cases to examine the gall bladder for typhoid bacilli, as many years' experience with a large amount of material has shown that if there is any typhoid infection in the body we are nearly always

able to cultivate typhoid bacilli from the gall bladder. On the other hand, there is no single case in which the pathologist has been able to cultivate typhoid bacilli from the gall bladder where the serum test turned out negative.

Typhoid fever has, of course, many complications, and among others there may be complications with mixed infection. Thus Ohlmacher reports two cases marked by hemorrhagic and purulent meningitis, both fatal. The typhoid bacillus was found pure in the diseased parts of the brain. In another case by the same author, a case of typhoid fever was attended by secondary streptococcus infection of the meninges. In this case the typhoid bacillus was found pure in the spleen and mesenteric glands, but cultures from the diseased parts of the brain and from the blood of the heart furnished both streptococci and typhoid bacilli.

In all these cases the diagnosis may be made in life in the absence always of previous infection with typhoid fever.

Treatment.—Now a word only as to the treatment of this case. The patient is doing well under a milk diet and an occasional dose (five or six grains) of lactophenin when the temperature reaches 101° F. We find that the comfort of the patient is much increased under the use of this remedy or of phenacetine. The mind is less confused, the sleep is less disturbed, the state of vigil is lessened also. We have no complications to combat thus far. Should the temperature reach 102° F. in the rectum we should immediately give the patient a cold bath. Where this precaution is adopted from the start we lose no cases of typhoid fever, barring the accidents of perforation and profuse hemorrhage. We adhere, in theory at least, to the Brand method, and bring down the temperature with cold baths at 68° to 70° F. All patients feel the benefit of this treatment, as a rule, and it is only in the exceptional case that one complains of it. The cold bath strengthens the heart and drives out the typhotoxine through the kidneys. Until we may discover some antitoxine, there is no real substitute for the cold bath. We could really ask nothing better if it could be adopted rigidly and from the start. If the patient goes to bed at once to economize the strength and receives the cold bath systematically, the mortality is reduced from fourteen to seven per cent., and the liability to both hemorrhage and perforation from three or five per cent. to one per cent. and a half or three per cent. But a good deal depends upon the time when the treatment is instituted. Thus, of thirty-two cases treated before the fifth day there was a loss of but one—that is, 3.1 per cent.; of twenty-eight cases treated before the tenth day there was a loss of six—that is, 21.4 per cent.; while of eleven cases which did not receive the treatment until after the tenth day there was a loss of four—that is, twenty-two per cent. I am quoting statistics now from a perfectly reliable source, though I forget the source. A cold or treatment late for such results.

But it is not always practicable to give the cold bath—that is, there are cases in which the patient, or more especially the friends, absolutely refuse the bath. Now here, of course, much will depend upon the convictions of the physician. He may nevertheless insist upon it and have it done, or he may compromise, and have it done imperfectly, or he may compromise still further, and give a cold sponging or use instead the modern antipyretics. These things are, therefore, all compromises. And like all compromises, they fail to furnish ideal results—that is, they fail to save some individual which would have been saved by the cold bath. I say nothing of the so-called abortive treatment, which can be of no value after the first week. We do give our patients a dose or two of calomel, and sometimes follow up the treatment with salol or naphthol when the discharges seem to be offensive. But we do not expect to accomplish anything curative in the sense of abortive in this way, because the micro-organisms which produce the disease have long since entered the blood, become colonized in the mesenteric glands, and especially in the gall bladder, where they develop their various toxins far out of the reach of any intestinal antiseptics. A medical friend of mine said to me on the street to-day: "There is a growing tendency to abstain from cold baths." Certainly there is. These tendencies are always present. The *laissez aller* is always easier than the *laissez faire*. The question of the treatment of typhoid fever resolves itself with many other questions into the right and the expedient. The right treatment insists upon the use of cold baths; the expedient substitutes them. This treatment reaches deeper than typhoid fever. It is a matter of the construction of individuals who practise medicine. I would say, were it not for fear of misconstruction, it is a question of character.

SPONTANEOUS ABSORPTION OF SENILE CATARACT, WITH RESTORATION OF VISION.

DISLOCATION OF NUCLEUS AND CAPSULE INTO THE ANTERIOR CHAMBER.

By F. W. MARLOW, M. D., M. R. C. S. E.,

SYRACUSE, N. Y.

Mrs. L. Irish, was operated upon by me ten years ago for cataract. She was at that time about seventy years old. Her left eye had been failing for twenty months, and her right for ten. The cataract in the former was quite ripe, in the latter still immature. The former only was operated upon, the resulting V. being $\frac{6}{8}$ partly.

Getting on well with one eye, she has never consented to operation on the second.

On account of some diminution of vision in the left eye she consulted me on November 18, 1898. I then observed that the pupil of the right eye was black. Closer inspection showed the small, brownish yellow cell nucleus lying in the lower part of the anterior chamber, half

concealed by the limbus and broad arcus senilis. Its edge was indented, and from each margin folds of what appeared to be the capsule of the lens passed upward, converging to a point in the anterior chamber almost level with the upper margin of the pupil. This membrane was for the most part transparent, its limits being very sharply defined, and dotted with minute opaque white spots.

The fundus could be seen without much difficulty, the only deviation from the normal noted being an atrophy of the chorioid immediately around the optic disc.

The pupil was five millimetres wide and showed no reaction whatever to light and convergence. The iris was tremulous. The pupil of the left eye responded moderately but promptly to these stimuli.

V. of R., with \pm 10 D. sph., is $\frac{3}{8}$.

V. of L., with corrections, was still $\frac{6}{8}$ partly, in spite of the presence in the pupil of a thin, tense membrane.

Although no history of injury could be obtained, the dilated and immobile conditions of the pupil, together with the condition of the lens, is suggestive of traumatism.

As has been pointed out by Pagenstecher and others, and confirmed by Priestley Smith during his investigations on the growth of the crystalline lens, the attachment of the lens to its suspensory ligament, and especially of its posterior surface to the hyaloid membrane of the vitreous, is much weaker in old age than in youth.

In view of the age of the patient, the blindness of the eye, and not a very high degree of intelligence, it is possible that a traumatism sufficient to loosen the attachments of the lens capsule may have occurred, without involving enough disturbance of visual function or of the patient's comfort to make her remember it.

It is most probable that the dislocation of the over-ripe cataract into the anterior chamber preceded its absorption, although no evidence on this point was forthcoming.

In the absence of a definite history of injury the case is reported as one of spontaneous origin.

SOME SUGGESTIONS ON THE TREATMENT OF PYORRHOEA ALVEOLARIS.*

By G. LENOX CURTIS, M. D.

In my remarks I shall not attempt to exhaust this subject, which is broader than the present status of knowledge. I will, however, make a few suggestions, with the view of drawing out discussion that may lead to widening this field. I shall not think it strange if some of my hearers disagree with me, for I differ somewhat with most authors upon the subject. I think that Dr. Pierce has fallen into the error made by some other writers who maintain that uric acid is the cause instead

* Read before the Alumni Association of the Boston Dental College, December 11, 1898.

of the result of rheumatism and gout, of which pyorrhœa alveolaris is a symptom, seen only in certain classes of the dyscrasia. I have found that it is not always safe to adopt some views, especially those found in some books. Not only dentists, but physicians sometimes depend too largely upon literature for their practice in most oral diseases.

Perhaps all dentists do not have facilities for thorough experimental work, but they certainly deserve credit for the persistent manner in which they have endeavored to cure, by devoting their time almost wholly to the treatment of a single symptom. I believe that very few recognize the importance of general treatment, with the view of eradicating from the system the conditions that aggravate this disagreeable and offensive malady. There are physicians—even those of prominence—who seem to fail to observe one symptom familiar to every dentist—that is, they do not appear to connect the local aspect with a systemic disorder. In both of these professions the lack of general knowledge concerning the intimacy of the systemic with the local (directly or indirectly) is something surprising. The present plan of medical teaching is far from being equal to that known to the educated dentist more familiar with oral diseases. The medical curriculum will not be effective until its students are better educated upon oral diseases. The ætiology of pyorrhœa alveolaris, or loculus alveolaris, to my mind, is best presented by Dr. Eugène S. Talbot, who attributes the principal cause to careless dentists and to the degeneracy of some of the oral tissues. The clinical features are best described by Dr. J. N. Farrar in his articles in the *Independent Practitioner*, April and September, 1886.

Among the local causes for which I believe careless dentists are responsible is the extraction of one or more teeth, leaving thereby imperfect antagonism, improper contour fillings, overlapping fillings between the teeth, ill-fitting root bands and plates, ligature, file, and emery-strip wounds; possibly too hard malleting is a factor; certainly bunglingly made regulating machines, V-shaped spaces between the teeth (whether caused by file or wedge) allow lodgment of food, salivary calculi, and cheesy deposits. Any local condition that leads to degeneracy, or any medicine that causes salivation, should not be overlooked in the diagnosis and treatment.

I regard rheumatism, gout, and syphilis as potent causes of this malady; but, of course, it does not necessarily follow that these affections always accompany pyorrhœa alveolaris. I sometimes think that physicians do not always appreciate the importance of retaining the natural teeth, or substituting artificial ones where only one or more are lost. As the treatment of local diseases more properly belongs to the dentist, and many of them do not thoroughly remove the deposits from the teeth, and a less number have a practical knowledge of the best principles in the treatment, I think moreurgi-

cal and medical education should be taught in dental colleges, and more dental education taught in medical colleges. Most dentists are general practitioners in their calling, attempting all parts, and do not follow exclusively any one branch until they find that they excel in it. Instead of advising their patients to go to a specialist for treatment of that in which they do not excel, they too often skim over that, making a feint at treating the disease, or, what is more unpardonable, adopt the "do-nothing plan," and tell their patients this trouble is incurable.

I believe pyorrhœa alveolaris can be cured. This I feel I can prove by tabulated cases. Treating this disease, while practised by dentists, belongs as much to surgery as the reduction of fractures. Of course, only the deft in skill can properly treat it. Dr. Dunlap truthfully said: "A doctor can be made in five years, but it requires twenty-five to make a first-class physician."

A clear knowledge of the condition of the patient is an important matter. The surgeon generally tries to learn this, while the dentist too often overlooks it. The restoration of the general health is essential to the cure of pyorrhœa alveolaris, but the restoration of the general health can not be accomplished so long as this particular disease exists in an aggravated form. The ordinary physicians rarely examine the mouth to ascertain whether there are sufficient teeth to masticate with, and overlook the common fact that there are often pyorrhœic pockets filled with bacteria and pus daily being mixed with the food, and continually carried into the stomach. Nearly all persons affected with this disease have dyspeptic ailments, anemia, blood poisoning; and, accompanying these, there may be various forms of neuralgia and, occasionally, mania. A physician would not expect to cure dyspepsia, or to cure phthisis, until he had first cured nasal catarrh, if present. I believe that the nails and the teeth are among the best indicators in diagnosis of rheumatism. They show certain signs long before other symptoms appear, except those found in the blood. They may be regarded as an index showing when to cease treatment for rheumatism. When the abrasions on the teeth lose their hypersensitiveness, and the nails lose their corrugations and lines, returning to their normal smoothness and flexibility, we well know that the rheumatic poisons have been eliminated. Can not the ridges so frequently found in the teeth be accounted for by prenatal influences, such as rheumatism during gestation? Why should not the teeth germ become marked as well as the nails? The hardness of enamel retains the ridges, while the nails change about every three months, and the indicator may be lost.

The examination of the blood is important in the diagnosis, as this paludum shows the presence of existing diseases. The examination of the blood is, I think, the strongest bias in diagnosis. In many diseases such evidences may, or may not, be found in the blood. These are always found before the objective or sub-

jective symptoms. They are the first to come and the last to leave. Dr. Robert L. Watkins maintains that fibrin is present in the blood in advance of the general symptoms of rheumatism, apoplexy, organic heart disease, fevers, etc., and is as variable in form as are the diseases themselves. Dr. Watkins has found in the blood of patients suffering from pyorrhoea alveolaris different varieties of fibrin, spores of syphilis, eczema, tuberculous matter, and the bacillus itself. He found these even when the diseases were not active. We may, therefore, reasonably base our hope of ascertaining the etiology of the disease by the study of the blood.

Dr. Talbot regards careless dentistry as the cause for the increase of pyorrhoea alveolaris. Dr. Beers touched the keynote when he said: "The gingival margin should not be wounded." When the gum has been wounded, the greatest care should be taken to heal the wound without infection, and especially is this true in cases of inherited tendencies. While the neurotic patient is prone to pyorrhoea alveolaris, exaggerated cases are not infrequent in the phlegmatic patient. Although no outward sign of lesion exists, it is often found that the pulps of some teeth involved are devitalized. Infected tissue from septic tooth canals is often classed as pyorrhoea alveolaris, and treated without first removing the cause, and from this the teeth are often lost. Whenever such teeth are extracted (in order to prevent the continuation of the disease) the sockets should be curetted and treated as open wounds, until filled in by granulation.

Patients naturally shrink from being hurt; but now that we can safely use a strong solution of cocaine, by first administering its antidote volasem, the treatment of pyorrhoea alveolaris is comparatively painless. I would not have it understood that I believe every tooth involved in this disease can be saved, or that an attempt should be made to save all teeth. To do the greatest amount of good, it is often necessary to make some sacrifice, but because a number of teeth are loose it does not follow that they should be extracted. The patients' wishes should be consulted, and as they look to their doctor for guidance, they are generally willing to accept his advice. I was recently asked by a dentist to see with him a case of pyorrhoea alveolaris that he had been treating for four years. He appeared satisfied with the results, for by the use of ligatures he had been able to hold in position several loose teeth; yet this was done to the detriment of those teeth to which they were fastened. The gums were hypertrophied, boggy, and purple, with evidence of calculi beneath them. Four of the teeth which had not been opened contained septic pulps.

Medical treatment for the disposition of degenerating cause should be given in conjunction with local treatment, and should be continued until the disease is eradicated, that is, the general health of the patient should receive careful attention. Septic canals should be cleaned and filled with a permanent material. He-

move all the calcareous deposits, ulcers, abscess sacs, carious bone, irritating roots, and in fact every source of irritation. The greatest care must be observed in curetting and dissecting away every particle of diseased tissue, so as to leave a fresh and healthy wound, which should be treated as such and encouraged to heal as rapidly as possible. Next, boil out all remaining debris with peroxide of hydrogen. The patient should be instructed to use a sterilizing mouth wash (electrozone is probably the best) every half hour, if possible, for twenty-four hours; then apply tincture of iodine sufficient to flood the wound around the roots. This treatment should be continued every two or three days, until the wounds are healed. Care should be observed to avoid bloodletting while treating the wound, lest it become infected.

The period of treatment is usually from one to two weeks. The fixation of teeth should be done as early as possible after the first operation by means of a splint, as devised by Dr. William L. Fish. Proper occlusion of the teeth is essential to prevent undue pressure on any one, and to facilitate mastication. Never use acids or mercury. Operate on a small part at a time. Stop treating the wound when it is healed. When the disease is so extensive that little attachment to the root remains, the pulp being vital, the extirpation of the pulp and the treatment of the canal, if septic, should be done. Instruct the patient to return when any irritation of the gum or jaws is noticed, and from every three to six months for examination. It is not always easy to fully impress upon the patient the importance of this advice. The irritant that caused the disease will reproduce it.

HYGIENE VERSUS DRUGS IN THE TREATMENT OF PULMONARY TUBERCULOSIS.*

By CHARLES L. MINOR, M.D.,
ASHVILLE, N. C.

IN choosing the subject of my remarks I have been prompted by the conviction that, despite all that has been said in its favor, the general practitioner, and often the specialist himself, is clinging too closely in his treatment of phthisis to the use of drugs, has no real familiarity with or active faith in the possibilities of hygienic and dietetic treatment, and seems to think that they, assisted possibly by climate, can do all that is necessary; there is danger lest by his faith in medicines he ruin the stomach, the only bulwark which stands between the pulmonary invalid and destruction. This faith in drugs and disuse of hygiene, I believe arises largely from the fact that a hygienic cure, to be satisfactorily carried out, demands of the doctor far more

* Read before the Mississippi Valley Medical Association, October 11, 1895.

pains and attention, a far closer oversight of his patients and their life, than is needed when he pins his faith to a series of prescriptions, and trusts, often too fondly, to the patient's taking them as ordered. Ever since the days when our ancestors lived in primitive simplicity, there seems to have existed in human nature an unquenchable faith in the existence of specifics for each disease, a faith of which patent-medicine venders make clever, if unscrupulous, use. Just as the medicine man of the prairies seeks to drive out sickness by bideous noises or horrible odors, so we, his more civilized brothers, too often hope by pouring drugs down our patient's throat to see the malady overcome. Indeed, in this especial disease, so great has been the number of drugs used that the great Laennec,* the father of auscultation, writing in 1819, bases an argument for the incurability of phthisis on this very fact. "One can not deny," says he, "the disease to be incurable when we see in turn tried against it almost every known medicinal substance, the most divers remedies, the most opposed drugs; when we daily see new medicines proposed, and note the resurrection of measures formerly extravagantly vaunted and now long forgotten." Writer after writer, after long experience, has had to confess the inutility of drugs. Yet if we but turn to the therapeutic columns of our medical journals we find receipt after receipt recommended for use in consumption.

As McLean well puts it, in a recent excellent article: † "It is easier to take medicine, it is pleasanter to be told we have only a little bronchitis"; and I might add, it is so easy for the doctor to dump a portion of his heavy responsibility on to the shoulders of some prescription, and to take refuge behind the authority of its introducer.

And yet, since the earliest days, there have not been wanting those who have raised their voices for a hygienic treatment. Celsus,‡ in his *De Medicina*, written in the time of Christ, gives so admirable a *résumé* of such a treatment that I shall trespass on your patience to quote a portion of it here: "If strength permits, one must make long sea voyages, change climate, and seek a denser air than that one lives in" (a reverse of our modern view). "Italy or Alexandria, for example, agree well; in the beginning, invalids are almost always able to make such a voyage, for the disease generally comes on in the most robust period of life—that is, from eighteen to thirty-five" (a statement he borrows from Hippocrates). "If they are not strong enough for long sea voyages, they can take short trips along the coast. If it is impossible to go to sea, one can be carried on a litter, or otherwise. The patient must give up all business and all that worries, must sleep

much, avoid catching cold—lest the cold destroy the advantages won by all these precautions—avoid indigestion, great heat or cold, keep the mouth and neck covered, check the cough by appropriate remedies, and try to suppress the fever, either by diet or abstinence from food. . . . Milk . . . can be given with much advantage. . . . If there is little or no fever one must have recourse to moderate exercise, especially walks and light rubbings. . . . It is wise to give food in the interval of the fever, and to use frictions. . . . But the means which hold first place are regimen, exercise in a carriage, sea voyages, and nourishing food. As they improve, the exercise must be increased, as also the rubbings and the food. Then let them rub themselves while holding the breath, and avoid for a long time wine, bathing, and sexual pleasures." Such was the advice obtainable in the time of Christ. Drugs, it is true, Celsus also, but far less strongly, recommended, but a hygienic and climatic cure was his ideal, and to-day we have not added very much to what he taught.

Come onward nineteen centuries, and let me quote the words of Lauth.* "Hygienic treatment alone can increase the general strength and give the body the force necessary for the struggle. All other means are but adjuncts; there is reason to apply them with judgment under certain special indications dependent on the clinical course of the disease, or on the constitution of the invalid," but, I would add, the real curative factor is and will always remain the intelligent and painstaking use of hygienic measures.

I realize that the faithful carrying out of such a course of treatment is tedious; that it demands on the part of both patient and doctor what the Germans well call "*ausdauer*," lasting-outness, perseverance; that it calls for the most complete cooperation of the patient with his doctor, and his implicit obedience. But we are dealing with a malady so dreadful that even the most heedless patient, if the facts are clearly set before him, will give us his cooperation; with a disease so insidious that even the most light-hearted doctor must realize the responsibility that is on him, and surely the results to be obtained—the happiness of the patient and of his loved ones, the satisfaction of work well and successfully done, will keep us up through it all.

To turn, then, to the hygienic and dietetic treatment of consumption in detail, I would embrace under those terms all such non-medical measures as are directed toward an increase of the vitality of the organism and its resistance to disease. Strictly speaking, this would include climate therapy; but, though I believe that this is but a branch of hygienic treatment, I will here neglect it, as it at least needs, with so lack of faith on the part of our profession, the advantages being too

* Laennec. *Traité de l'auscultation médiate*, édition de la Faculté de méd., Paris, 1819.

1896.

patent to need demonstration, and confine myself to the other branches of the method—in brief, *exercise, gymnastics, massage, hydrotherapy, rest and sleep, diet, amusements, clothing, and quarters*. To all, or some of these, a partial and, as I believe, half-hearted attention is given, but I am convinced that only the most minute and careful regard to each detail can yield the best results.

Generally it is to the pharmaceutical and not to the more important hygienic precautions that attention is given, so that the average patient supposes that if he faithfully takes the drugs ordered he is doing all that is needed, and follows in the far more important matter of the regulation of his daily life his own sweet will. And for this he is not to blame, when you consider that such hygienic advice as is given, which generally implies a complete reversal of the patient's ideas of living, is not written down and emphasized, but talked to him in the course of a consultation.

The measures are usually specified too indefinitely. To tell a patient to "take plenty of fresh air," to "take enough exercise," to "eat plentifully," to "get enough sleep" is as unsatisfactory as to say "Take enough calomel," "Take a good dose of quinine." How is he to know what is enough, or what too much? Even so good an authority as Powell* thinks that he has said all that is necessary when he says: "The hygienic surroundings must be strictly looked to and as much fresh air as is compatible with the season of the year and the patient's strength be allowed." No one who at any European health resort has seen the admirable effects of the strictly ordered and strictly carried-out discipline of every detail of the patient's life, but must compare its care with the carelessness so common in this land of the free, where patients seem to think that by drinking a given number of glasses of mineral water, or staying a certain number of hours in the open air, they have fulfilled every requirement for their recovery, and feel free to live in every other way as suits them best.

With all invalids, but with the consumptive more especially, it is essential that his life be closely looked to; that he be given written directions, which are to be to him the tables of the law, by obedience to which he is to reach the promised land.

If he is to recover it can only be as a reward of ceaseless vigilance and effort; to no half-hearted seeker after pulmonary health will healing come; if color is to return to his cheeks and vigor to his limbs, if he is to get the upper hand of the disease he is fighting, both he and his doctor must work, and work hard. Given a patient—and such are not too common—who is willing intelligently to use every means, and a doctor who find no detail too trivial for attention where it affects his charge's health, and hygiene, save in very advanced cases, will achieve results which will fully repay us for our toil. But I have already

taken too much of your time, and must hasten to the matter of the carrying out of such a cure. When a patient presents himself for treatment, after a thorough history is taken, after a carefully recorded examination and diagnosis, after as clear a conception as possible has been formed of the exact pathological conditions in the lungs, we medical men are apt to think first and foremost, What medicine shall I give here? If, on the contrary, we would start first to plan and write out (that forgetfulness or misconception may not be pleaded) the details of our patient's life; if we give him a carefully prepared dietary rather of the things that may need to be avoided than of those that can be taken—for all food that is not positively harmful is of value—if we give rules for his exercise accurately stated, for his clothing, amusements, bathing, etc.—in short, for every feature of his life; if we sufficiently impress on him the paramount importance of minute attention to these things and exact a promise of obedience, we will find not only that we will be apt to have made a good step in that most important matter of winning our patient's confidence, but that the portion of our orders devoted to drugs can be made small indeed, without any decrease, possibly an increase, in the excellence of our results.

I personally have found it convenient to classify all hygienic measures under three heads, and this is accurate enough for all practical purposes: Those affecting the patient's surroundings, life, and exercise.

Under surroundings I place all that relates to the situation of his house and the lay of the land around it; the conditions of that house as to sanitation, elevation, exposure, ventilation, and heating; the choosing of his room, its heating, ventilation, and temperature, etc.; his clothing, its weight, nature, and forms. Under conditions affecting his life I would place the hours he keeps, the amount of his sleep, the hours of his meals, and the arrangement of his diet, his bathing and hydrotherapeutic measures, the care of his mouth and voice, and that most important item, the nature and extent of his amusements. Under exercises, I place rules as to walking, its limits, advantages, and abuse, as to massage when needed, and careful details as to pulmonary gymnastics, which I use largely in proper cases.

Planned out in this way not a feature of his life need escape us, and we can keep it all under our control.

As to the special features, each man has his own views. I will only note here certain details I consider most important. The situation of the house and the especial avoidance of a damp subsoil, shown long since by Bowditch to have a causative relation to tuberculosis, should never be left to the patient's choice. That common fault of many houses, overwarm rooms and ice-cold corridors, scarcely needs to be mentioned. The heating is all-important, and I have found that though, with care, excellent results can be had in furnace-heated houses, it demands more labor than where steam heat is available.

* Powell. *Doctors of the Lung*, London, 1893.

The water box of a furnace is utterly inadequate to supply the proper amount of moisture to the superheated, bone-dry air its flues deliver. When not to be avoided, the bad effects of a furnace can be largely done away with by placing a tin water can in each flue, and the rapidity with which they are evaporated best shows how much they are needed. They never give off steam, which would be harmful, but simply restore to the air its normal coefficient of moisture, and are an excellent preventive of catarrh. In the bedroom no furnace heat should be allowed under any circumstances, the flue pipe being closed at the furnace as well as in the flue, and heating of the room being intrusted to the open fireplace. The selection of the room as much as of the house must not be left to the patient's judgment. In such matters he has none. The sharing of his room with another, even his wife, is not advisable, if possibly to be avoided. He needs all the air he can get, and should not be called upon to share it with another. A wall thermometer should be part of the furniture of every consumptive's room; 65° F. is the ideal in winter. Over 70° should be forbidden, too hot being far worse than too cold. The bed, where he spends one third of his life, must be so situated as to avoid direct draughts from the windows, and the bed covers, while warm, must be light, and only single beds tolerated.

The average consumptive, when left to himself, will be found to be very much too warmly clad. Thick, sweat-producing clothing serves no good purpose, weighs down the weakened body, relaxes the superficial capillaries, and does harm. The rule of wool next to the skin all the year, which needs no advocate before a medical assembly, is wonderfully difficult to enforce with the fair sex; yet no one who has worn it even in summer but knows that if of proper thinness and texture it is fully as cool as cotton and less likely to chill when we perspire; nevertheless, partly through its expense and partly through prejudice, it will be impossible to obtain in many cases. Whatever the material, if it is so cut as to leave exposed the apices of the lungs, and thus subject them to chilling, it is bad. What is known to the trade as the high or French neck should be insisted on.

Of the harmfulness in a respiratory trouble of corsets, or at least of tight ones (did any woman ever admit they were tight?), I need not here speak; mullers, so popular everywhere—those common makers of weak throats—are not, I believe, sufficiently recognized as a curse to be banned; while any one who has undressed a consumptive and noted the perspiring skin under the popular and worse than useless chest protector will realize the harm it does.

No patient needs more sleep than the phthisical. The old and recently revived view of tuberculosis as a nervous disease may not be well founded, but the nervous system in common with all the body is exhausted and over irritable, and sleep is its best restorative; therefore, let the patient keep early hours, and see that he

has an exact hour to be in bed, never later than ten, and let him get, if possible, a good nine hours' rest.

There exists among the laity a widespread misapprehension as to the harmfulness of a cold sleeping room, and the fact that if the body be but properly protected from evaporation and chilling there need be no fear of catching cold, even if the surrounding air be at zero, is generally unknown. This fact is borne out, however, by innumerable observations. The statement of Ransome, in Park's *Hygiene*, that the artillery of the Afghan field force, wintering in the bitter cold of Candahar, slept out in tents and preserved good health, while the infantry in barracks suffered severely from pneumonia, is but one of many proofs of this fact; yet a large number of all Americans, especially the consumptives, whatever air they may get in the daytime, habitually sleep in winter in close and unventilated rooms, expecting to get from a small crack of open window enough oxygen for the demands of their economy, and thus spending one third of their life under the very conditions they should most sedulously avoid. As Ransome, in another place,* puts it, "Fresh air day and night must be admitted to all living rooms and bedrooms; and the present foolish dread of what is called 'night air' must be overcome." It is not possible all at once to accustom people to proper conditions. In this matter the process has to be gradual: first, possibly, a small crack, increased nightly till one whole window, and finally two or more are left open; but save in a few generally advanced cases, where it increases the cough, it is soon tolerated, and finally liked.

Mealtime, after what I have said of nutrition in this malady, I need hardly say is the most important hour of the day. The fastidiousness of the pulmonary patient makes it hard to render this hour attractive as it should be, but with increasing outdoor life and exercise the appetite generally returns. Never take the patient's statement that he is eating well at its face value. Cross-questioning will often show that he has no idea of what that means. Exact a record of each meal in the beginning with all cases. When once the appetite is recovered it becomes unnecessary. The usual three meals a day in light cases will often do, but with the addition, where it does not overload the stomach or kill appetite, of a small, nutritious, not necessarily alcoholic, "pick-me-up" at eleven, four, and at bed. These latter supply the organism, whose rate of oxidation is too rapid, with the necessary fuel to carry them to the next meal, and prevent the gone feeling so apt to come on before that time.

The consumptive who has been overfed, who has had rammed down his throat more than he could digest or assimilate, and whose stomach has "gone on a strike," is no rare sight, and should warn us from falling into the error of taxing a debilitated organ beyond its powers in the hope of increasing nutrition.

* Ransome. *Treatise on Phthisis*, London, 1890.

A quiet rest on the bed for half an hour before mealtime and, if gastric catarrh is prominent, the usual glass of hot water sipped meanwhile, I have found very important, as preparing the organ for its work, for the tired man can never properly digest.

Likewise the hour after dinner had best be spent quietly reading or talking, and all walks or drives postponed till digestion is well under way. In this land of fast eaters deliberation at table can hardly be had, but it is useless to expect an organ weakened by disease to dispose of large masses of unchewed and bolted food; yet the examination of the vomitus of tubercular patients will show us how often their meals reach the stomach in this shape.

In cases where the gastric functions are very weak, I get the best results by frequent small meals every one or two hours, with small amounts of predigested or highly nutritious foods, and have thus overcome severe anorexias and *Auseas*, and been able, by degrees, to resume regular meals. But the majority of cases which demand such measures have passed the point when more than amelioration of symptoms can be hoped for.

If the doctor will, in delicate stomach cases, himself plan the bill of fare from day to day, he will find himself rewarded for his pains, and the good effect can be heightened and the appetite stimulated by not letting the patient know beforehand what he is to eat, a knowledge of what is coming at the next meal often depriving a patient of any desire for the food, while a pleasant surprise, on the contrary, is a good appetizant.

In this connection there is no doctor but can advantageously cultivate, with his wife's assistance, a knowledge of cookery, specific directions how to broil a steak, how properly to prepare sweetbreads (a thing, by the way, rarely done), how to cook chops daintily, and fifty other things, being invaluable in a land where good cookery is not always the rule.

The amusements of our patients will tax our ingenuity, for in no item are they so apt to disobey. The average American is not willing, even when his health depends on it, to obey any one, and supposes that if he has taken his medicines he has fulfilled his duty to the doctor and the disease, and believes that how he shall spend his time, where he shall go, and how amuse himself are matters which concern him alone.

It is necessary, therefore, in the beginning, to have it definitely understood that implicit obedience must be given the doctor. Most patients will be rational enough to appreciate that you are working for their good; and as for that class who are doing what they do, as if it were a favor to you, and feel at liberty to disobey when they please, it is wiser, after a patient trial, to throw up the case, and let them seek other aid. In the long run we will gain rather than lose in influence with our patients by such a course.

I have found the greatest difficulty in managing young girls, whose heedless search for pleasure blinds

them to any considerations, save the enjoyment of the moment; older people are generally more manageable, and yield proportionately better results. I have often got better success with relatively severe cases in the latter class than in much lighter ones in the former.

I recall two patients who were under my care: one a young and very lovely girl with slight apical catarrh and consolidation, with no breaking down of tissue; the other, a middle-aged single woman of great determination, with a far more extensive and serious involvement of most of the upper right lobe.

Both were put on a strict hygienic cure with very little medicine: the young girl was occupied with the enjoyment of the attention of many admirers, and unable to resist the temptation to imprudence on every side, or to consistently carry out orders; the older woman devoted her whole heart and soul to the task of getting well, neglected no precaution, followed directions faithfully, and is to-day well and carrying on her calling in an Eastern city successfully; while the other, as I learn, is slowly but surely going down the long hill we all know so well, and approaching a grave she could, had she had but sufficient seriousness of purpose, have avoided.

Thinking of them, the pregnant truth so well put by Dr. McLean, in the article already referred to, is forced upon us—"If the phthisical patient would live, he must work for it."

The surroundings and company of our patients must be as cheerful as possible. The melancholy and depressed patient fights an uphill fight. All games which call for violent physical exertion, like tennis, and overtax a weakened muscular system, ought to be avoided; while I would add my voice to the many which have lately been raised in favor of golf, of which I can speak from experience, as the ideal mild, but interesting, outdoor sport, though in the beginning but a small part of the course should be gone over. Those indoor amusements which subject the patient to overheated, dusty, or vitiated air are, above all, to be avoided: theatres, dancing assemblies, parties, even crowded parlors, artificially lighted, all place the patient under unfavorable surroundings, and at the same time overtax his nervous system, and are not to be heard of.

Church, though hardly to be classed as an amusement, is not to be forgotten. If not draughty or too hot, I have never known it to be harmful.

Horseback, driving, and walking come more properly under the head of exercise, but of amusements they are possibly the best and most helpful.

Night amusements are generally to be avoided, not because there is anything in non-malarious regions in the prevalent fear of night air—certainly in the mountains experience shows its fallacy—but because they come at the end of the day, when the strength is lowest, because they disturb the early bed hour, and because they are only to be had in artificially lighted and generally

overheated halls. Sexual enjoyments should be entirely or all but entirely forbidden; nothing so exhausts the vitality and prostrates the strength. Unfortunately, a large number of patients experience an access of sexual passion in this disease, but reason will generally serve to control them.

Rest for the consumptive can be viewed from two points: rest for the light, incipient, afebrile case, and rest for those who have fever.

To the former rest is important before meals and after exertion, but to the latter it becomes essential, and is our best antipyretic.

With temperature ranging over 100.4° it should be obligatory; and even at 99.4° exercise should be very carefully limited. Rest in a reclining chair, well wrapped up, outdoors, is generally pleasant enough, and certainly most effective; the organism, spared any waste of its forces, can turn itself with undivided strength to combating the disease.

After a faithful trial of it, let me, save in those hopeless cases where anything else is impossible, protest against the custom of putting the tubercular patient to bed for his fever.

Put him in bed and you do a violence to his spirits and hopes which he can ill tolerate, and which often turns the balance to the wrong side; let him, if need be, while equally prone and quiet, lie *on*, not *in*, the bed, and keep on his clothes, and he does not feel, as otherwise he would, that the game is up.

Moreover, bed robs him of what little strength he still has, and in my experience such an order has generally been the beginning of the end.

In patients whose cases are not hopeless the reclining chair in the open air is infinitely to be preferred to any bed. There they can pass their day from ten till four or eight, according to the season, warmly wrapped, reading or talking and enjoying themselves, only provided that that most lamentable invalid's habit of talking of symptoms be forbidden. Exact of your patients a promise not to talk over their cases, or to take their own temperatures, or to follow their own gains or losses of weight, and you have accomplished much.

Hydrotherapy in phthisis has, among the profession, not the position it deserves. It has suffered in the past as much from the untempered zeal of its advocates as from the way in which those unfamiliar with it tried to apply it. The elaborate apparatus illustrated in the writings of its apostles, as in Baruch's recent excellent work, are too elaborate, costly, and cumbersome for general use, and there is need of some simple yet fairly accurate means of availing ourselves of its undeniable advantages in the patient's house. Incidentally, I would say that in phthisis many, if not all, of the excellent results it offers can be got with no more complicated apparatus than a tin tub, a bath thermometer, a big sponge, salt, and a rough Turkish towel.

(To be concluded.)

DR. GEORGE BODINGTON (1840) AND THE OPEN-AIR TREATMENT OF CONSUMPTION.

By A. TUCKER WISE, M.D.
DIPLOME SUISSE FÉDÉRAL: M. R. C. S., L.R.C.P. (LOND.),
MONTREUX, SWITZERLAND.

I POINTED out some years ago* that the late Dr. George Bodington, of Sutton Coldfield, Warwickshire, was the first to devise and carry out the present system of generous diet and open-air exposure for the cure of consumption.

In those days (1840), before the theory of "phlogiston" had collapsed under the influence of microscopic pathology, he had many difficulties to contend against, and his plan of treatment, although successful with a certain number of cases, met with such derision and contempt that he finally gave up the practice, taking lunatics into his house sanatorium instead of consumptives—a laudable course to pursue in his case, as he was returning good for evil to the class who criticised and reviled his project.

The effect of adopting a suitable diet and fresh country air for the treatment of phthisis is rather ancient history, but Bodington grasped the points of their efficacy and brought these remedial agents into systematic working order. Much that he has written in a faded little volume of some sixty pages might be reproduced as a fresh article on the dietetic and open-air treatment of consumption.

Why so many writers on this subject represent the method as having been "made in Germany" I am unable to say. Certainly, Dr. Brehmer carried it out with satisfactory results in 1860, but the plan had been clearly laid down and described by Bodington, who practised it twenty years previous to Brehmer, and who published his success with the cases which were submitted to his scheme of treatment.

Our attention has been directed recently to the remarkable results reported as having occurred under the system of feeding and fresh air as conducted in the Black Forest, a climate which has been compared to that of the English lake district in winter! There is no question as to the efficacy of overfeeding and fresh air in those cases which are fortunate enough to possess digestive organs fairly strong and unimpaired; but we must not lose sight of the highly important part that climate plays—especially mountain air—in the cure of pulmonary consumption.

One good effect following the success of sanatoriums established in inferior climates will be to stimulate the scheme of providing similar institutions in England, where a great deal of what is lacking in climate can be made up in a nutritious and digestible dietary. There is no country in Europe where good food is so cheap and abundant, or meat, fish, poultry, and game of a better quality. The advantage also of patients being treated

* *Upon Winter in its Medical Aspects*, 1884.

by medical men of their own nationality who have an intuitive knowledge of the national constitution—are familiar with the habits and customs of English people and their requirements—is not to be forgotten.

Personally, I am sorry to see our well-tried old remedy—Alpine climate—temporarily slighted in favor of rival sanatoriums with quaint innovations, but in the main simply carrying out effectually the treatment originated by Bodington, from whose *Essay on the Cure of Pulmonary Consumption on Principles Natural, Rational, and Successful* I may be permitted to quote. He writes: "I should recommend to one thus consuming away, under the influence of this *wasting disease*, a nutritious diet of mild, fresh animal and farinaceous food, aided by the stimulus of a proper quantity of wine, having regard to the general state and condition of the patient. . . . I have, as will be found by a perusal of the following pages, employed a nutritious and moderately stimulating diet with much success; and without that I do not think the other means could have been so effectual or the treatment complete. . . . I have taken for the purpose a house in every respect adapted, and near to my own residence, for the reception of patients of this class. . . . It is presumed that the advantages to be derived from systematic arrangements with regard to exercise, diet, and general treatment, with the watchfulness daily, nay, almost hourly, over the patient of a medical superintendent, great advantages may be obtained by the consumptive patient treated in this way." Speaking of the therapeutic agents in use at that time, in 1839, he continues: "One mode of treatment consists in shutting the patients up in a close room, to exclude, as far as possible, the access of the atmospheric air; and thus forcing them to breathe over and over again the same foul air contaminated with the diseased effluvia of their own persons . . . this is indeed a treatment founded on the most erroneous principles." Referring to the inhalation of gases of various kinds, Bodington says: "The only gas fit for the lungs is the pure atmosphere freely administered, without fear; its privation is the most constant and frequent cause of the progress of the disease. To live in and breathe freely the open air, without being deterred by the wind or weather, is one important and essential remedy in arresting its progress; one about which there appears to have generally prevailed a groundless alarm lest the consumptive patient should take cold. . . . Farmers, shepherds, ploughmen, etc., are rarely liable to consumption, living constantly in the open air; whilst the inhabitants of towns and persons living much in close rooms, or whose occupations confine them many hours within doors, are its victims. The habits of these latter ought, in the treatment of the disease, to be made to resemble as much as possible those of the former class, as respects air and exercise, in order to effect a cure. . . . I come now to the most important remedial agent in the cure of consumption, that of the free use of a pure atmosphere. . . .

"The abode of the patient should be in an airy house in the country; . . . the patient ought never to be deterred by the state of the weather from exercise in the open air; if wet and rainy, a covered vehicle should be employed, with open windows. The cold is never too severe for the consumptive patient in this climate; the cooler the air which passes into the lungs the greater will be the benefit the patient will derive . . . and means applied to stimulate and invigorate the nutritive, sanguiferous, and muscular powers; wine and such nourishing diet as the stomach could bear, and by means applied to soothe and allay nervous excitement locally and generally. . . . Apartments should be kept cool and airy, corresponding to the external atmosphere, which should be courted and indulged in to the utmost."

After impressing on the reader the necessity of a generous diet, consisting of fresh meats, eggs, farinaceous food, beef tea, milk, etc., as much as the digestion could bear, with wine or wine and water, according to circumstances, he concludes by the relation of some cases, and a reiteration that the bedroom should be cool, airy, and properly ventilated, and the sitting room should have the window wide open.

I have quoted Dr. George Bodington at some length in the endeavor to point out by his own words and practice that we must regard him as the originator and introducer of the modern treatment of pulmonary tuberculosis. I am not aware of any one having forestalled him in clearly laying down the principles which now guide us in all health resorts and sanatoriums devoted to the cure of consumption.

Bodington must be accredited, too, with the courage of his opinions, for in those days of antiphlogistic remedies it was a bold, intelligent innovation deserving of all recognition and praise. Even that distinguished physician Sir James Clark sarcastically alluded to it at the time as the "beefsteak and porter system," which he decidedly condemned.

Therapeutical Notes.

Salicylated Gelatin for Eczema.—Schwimmer (*Wiener medizinische Presse; Journal de médecine de Paris*, November 20th) gives the following:

R Salicylic acid	10 parts;
Glycerin	10 "
Gelatin	30 "
Water	30 "

Dissolve by the aid of heat. The author recommends this application for vesicular eczema.

The Treatment of Baldness.—Barie (*Cronica médica*, October 31st) gives the following:

R Hydrochloric acid	75 drops;
Alcohol	2,250 "

M.

Rub the hairy scalp every night with this liquid and the falling of hair will cease.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

FRANK P. FOSTER, M.D.

NEW YORK, SATURDAY, JANUARY 14, 1899.

SANANDA EST HAVANA.

SINCE it is not the present intention of the American people to hold Cuba indefinitely, it is not unnatural for them to ask why they should pay for such an enormous work as that of bringing Havana into such a condition that it will be fit for civilized people to live in, and cease to be a nursery of yellow fever and other pestilential disease. But, while it is quite proper for us to endeavor to make an arrangement that will fix the ultimate responsibility for the cost on the Cubans themselves, we can not afford to let any difficulty in effecting such an arrangement stand in the way of immediate action on our part. Havana must be regenerated for our own sake, and, even if it were certain that we should never get back any portion of the cost of accomplishing the work, we ought to undertake it at once. Millions of dollars' damage to American trade, especially in the Gulf States, is entailed by every considerable outbreak of yellow fever on our soil. Often in a single year the loss amounts to more than enough to pay for the work of putting an end to the danger once for all. There is only one way of doing this, and that is by extending to the Cuban cities, and particularly Havana, the sanitation that is seen in our own large cities and in those of all other civilized countries.

We can not overlook the magnitude of the task, as one may satisfy himself by studying General Greene's report, published in the *New York Times* for January 1st. And we must not expect such a huge cess-pool as Havana to be cleansed within the few months that remain to us before the next annual summer outbreak of yellow fever takes place. It is true that the late Colonel Waring declared that the work much be done before the 1st of June, but we fear that such speed is hardly practicable. An entire sewerage system has to be created and practically all the houses connected with it. We learn from General Greene's report that what few sewers there are, built at the expense of persons whose houses they drain, are of unknown course, no records or maps relating to them having ever been made, and, even were that not the case, there is little probability that these few sewers could be turned to account as portion of an adequate system of drainage. Practically, too, the whole

city should be repaved, with the removal, so far as possible, of the soil beneath the present pavements, and in the unpaved streets, for it must be reeking with the filth that has sunk into it continually for generations.

Together with all this mechanical work, there must be an enlightened and efficient sanitary board acting under regulations carefully drawn to meet the requirements of the town. All these needs are pressing. They should be met immediately. We shall not have done our full duty to the people of Cuba or to ourselves if we allow niggardliness to hold us back from meeting them completely and with all possible promptness.

DIPLOMA MILLS.

IN our issue for December 31st we expressed a curiosity to know what the "Independent Medical College of Chicago" was. We have received an answer in the shape of a communication from Dr. J. A. Egan, secretary of the Illinois State Board of Health, from which we gather that it is, as we suspected, a "diploma mill."

The existence of these "diploma mills" has done more to damage the profession of medicine in the United States and to lower its prestige in other countries than all other considerations put together. Philadelphia was at one time the headquarters of these fraudulent institutions, but it has purged itself of the stigma. Now it appears that, owing to the faulty condition of the law, the State of Illinois is the principal centre of the abomination. We feel satisfied, however, that this reproach will not very long be permitted to disgrace that State, for the members of the medical profession, reputable schools, medical bodies, and individuals are bestirring themselves to wipe it off the escutcheon of the State, and with the aid of a thoroughly enlightened governor, such as Governor Tanner has shown himself to be, they are very likely to succeed.

The mischief lies not solely in the fact that a few hundred incompetent, though legally qualified, practitioners are thrown loose upon the various States of this country to practise where they like with their bogus diplomas, since the colleges are legally incorporated, save in States like New York, where a State examination is required of all candidates prior to the graduation of their diplomas as licenses to practise, but it shows itself still more widely in the want of reciprocity abroad, of which we complain. It must not be expected that foreign countries can well afford to recognize between all the unneeded qualifications of the country gentlemen; and while this is so, it is not surprising that the United States is the only one of civilized nations to any

in the world, it is to be feared that the *average* value of American diplomas abroad is greatly depreciated by virtue of these fraudulent schools. For it must be remembered that, save in exceptional circumstances, it is not the men from the best American colleges that leave their native country to practise elsewhere. They are tolerably sure of success at home. But it is to a large extent the holders of diplomas from these diploma mills who flaunt their "American" diplomas in foreign countries, as in the case of the gentleman who advertised his examination in India for the M. D. degree of the Independent Medical College of Chicago, to which we referred in our issue for December 31st.

These blots upon our profession, and we may add upon our country, inevitably lower the average status of our professional men abroad. It is no answer to criticism to say that at home such diplomas are held of no account by the reputable colleges and members of the profession. The obvious reply is, "They are granted by regularly constituted and legalized colleges whose diplomas confer the right to practise at home. You may have others, but if so we should welcome more graduates from them, and spare you as many of these to your own country as possible."

The whole difficulty seems to lie in the fact that in Illinois, and possibly in other States also, "it has been possible," to quote from an open letter addressed to Governor Tanner by the State board of health for Illinois, "for any three or more persons to obtain a charter from the secretary of state for a nominal fee, for the organization of any institution for an educational purpose. As a result of this there are at present in the State (of Illinois) over two dozen fraudulent educational institutions, aptly termed 'diploma mills,' which confer degrees in medicine, pharmacy, law, dentistry, divinity, arts and sciences, etc., upon any applicant in Illinois, in the United States, or anywhere in the inhabitable world, who possesses the necessary fee. This varies from five dollars to one hundred dollars, depending entirely upon the credulity and gullibility of the applicant."

In this letter various quotations are given to show the general opinion in the United States concerning this matter. In one of them, however, a quotation from the *Report of the Committee on Foreign Relations of Dental Faculties*, Omaha, August, 1898, the somewhat incorrect and unjust statement occurs: "The task of securing the repeal of the vicious law is too great for the courage of its (sc. the State of Illinois') reputable men, for ignorance and vice have struck hands in its maintenance." The present action of the State board of health, and the continuous agitation that has for some

time been kept up, and which it is now hoped is within range of success, are evidence to the contrary.

Now, inasmuch as we are informed that the law of Illinois gives to the secretary of state no discretion in the issuance of such educational charters, it being obligatory upon him to grant them whenever an application is properly made and the fee paid, it is clear that the authorities are not personally to blame. But it is also equally clear that an amendment of the law is required, and to this end the State board of health for Illinois has addressed to Governor Tanner the open letter before referred to asking for his aid in the matter. The course proposed by the board is to confer the power of issuing charters on some educational body in the State, which it is proposed should also have power to amend or revoke the charters for sufficient cause at its discretion.

This latter clause is of the utmost importance, for it by no means follows that an institution which begins well will not at some future time fall far below the desired standard.

At the same time we can not altogether exonerate those States and countries which take no steps toward establishing, as has been done by the State of New York, some practical limited examination as a *sine qua non* of the legalization of a diploma, no matter whence obtained. Such examinations should be as purely practical and as free from mere scholastic requirements as possible. If that were the case it would exclude the holders of bogus diplomas, compel the holders of reputable diplomas, who may be a little rusty, to polish themselves up to date, while those who come fresh from modern schools would, of course, find in it no barrier at all.

The Illinois State Board of Health has our hearty sympathy in the efforts it is at present making to remove this foul blot from the escutcheons of the State, the American medical profession, and the country.

MINOR PARAGRAPHS.

A CASE OF INTESTINAL MYIASIS.

MALEI (*Riforma medica*, 1898, No. 167; *Centralblatt für innere Medizin*, December 24th) reports the case of a woman, twenty-two years old, a teacher, who regularly in summer passed with the faeces little maggots that displayed lively movements. Examination showed that they were the maggots of *Sarcophaga* [*Sarcophila?*] *carminia*. Mention is made of Joseph's account of this affection in 1887, and the remark is added that it sometimes gives rise to severe symptoms, such as abdominal pains, epileptic seizures, vertigo, vomiting of blood, and anaemia. It is to be presumed that the ova are swallowed, escape the action of the digestive juices, and attach themselves to the intestinal wall, where they may live for days together without air.

THE PROMISCUOUS SALE OF ABORTIFACIENTS.

SOME time ago an ingenious blackmailing scheme was extensively practised in England. Newspapers there, as well as in some parts of this country, habitually accept advertisements of proprietary medicines which, under the ostensible purpose of "correcting female irregularities," are really meant to attract the attention of women whose desire it is, for whatever reason, to procure abortion on themselves. The names and addresses of women who had written for these remedies were used for the purpose of sending threatening letters, telling the victims that unless they remitted the sum of two guineas to cover costs and promised solemnly never to again attempt to commit the awful crime of procuring abortion, criminal proceedings would be instituted against them. Some one had the courage to expose this diabolical fraud, with the result that the perpetrators were brought to trial. Incidentally, attention was directed to the subject of the advertisement of such nostrums in even reputable newspapers, and the judge at once stated that the newspapers advertising remedies which purported, or were clearly meant, to be abortifacient, were accessories before the fact to the crime of procuring abortion, and were therefore liable to prosecution. The police authorities of London immediately acted upon this momentous decision and issued a proclamation, stating that all newspapers which continued to publish advertisements of that character would, after being duly warned, be held liable to criminal prosecution. We commend the promptitude of this action on the part of the London police, and recommend both the English judge's dictum and the action of the police to the law authorities in this country for imitation.

A FOREIGN BODY IN THE EUSTACHIAN TUBE.

TRAUTMANN (*Münchener medizinische Wochenschrift*; *Wiener klinische Wochenschrift*, December 18th) relates a case in which, in some unknown manner, a cherry-stone became lodged in the Eustachian tube, rendering the passage impervious to air. The air contained in the tube was absorbed, and this was followed by depression of the drum membrane and reduction of the power of hearing. Inflammation was set up in the tube and extended to the middle ear, resulting in perforation of the membrana tympani and chronic suppuration. One day, while the ear was being washed out, the cherry-stone was expelled into the throat, and the subjective symptoms ceased at once. They had consisted of an annoying sense of dragging in the side of the throat, pressure in the ear, pain on swallowing, and confusion in the head.

A NEW GERMAN OPHTHALMOLOGICAL JOURNAL.

WE have received the prospectus of the *Zeitschrift für Augenheilkunde*, the publication of which begins this month. It is to be edited by Professor Kuhnt, of Königsberg, and Professor von Michel, of Würzburg. It is to be published in Berlin, by S. Karger, and will appear in monthly numbers of about eighty pages each.

AN INAUDIBLE SUGGESTION.

THE *Montreal Medical Journal* for November (M. J. *ici*, January) refers to a recent address by Sir James Crichton Browne before the Pharmaceutical Society of Great Britain, in which that gentleman spoke of "the

innate stupidity of the average homicidal poisoner in choosing the means for disposing of his victim," and expressed wonder that such poisoners did not use agents that would "perplex the clinical observer, baffle the pathologist, and set at naught the skill of the analyst." Surely Sir James Crichton Browne can not have reflected upon the chance of his address coming to the attention of persons disposed to homicide, or he would not have cast out suggestions by which they might profit. Poisoners do not need to be instructed.

ICHTHYOL IS THE TREATMENT OF SMALL-POX.

MUCH effort has been directed toward the prevention of pitting as the result of small-pox, but this, it seems, is not all that is aimed at in the employment of ichthyol. Hoerschell-Mann, a St. Petersburg physician (*Klinisch-therapeutische Wochenschrift*; *Gazette hebdomadaire de médecine et de chirurgie*, December 25th), finds that applications of a mixture of ten parts of ichthyol and eighty parts of lanolin prevent pustulation and decidedly abbreviate the course of the cutaneous manifestations of the disease.

"TO THE LORE."

THE *International Dental Journal* for January contains a very interesting and readable article on "Tooth Lore, from the pen of Dr. George L. Parmelee. The various myths, superstitions, etc., attaching to the teeth among different peoples, north, south, east, and west, are commented on; history, poetry, bibliography, all are drawn upon for material, which is put together into a very readable article.

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 7, 1899:

Week ending Dec. 31. Week ending Jan. 7.

DISEASES.	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	18	9	15	12
Scarlet fever.....	141	11	132	4
Cerebro-spinal meningitis.....	0	11	0	4
Whooping-cough.....	142	9	127	8
Diphtheria.....	155	23	149	34
Group.....	16	11	13	7
Tuberculosis.....	129	143	189	177
Small pox.....	3	0	1	0
Chicken pox.....	11	0	29	0

Immunization against Morphine. Carlo Goiffredi (*Giornale internazionale di scienza e medicina*, November 15th) thus concludes a paper on his further researches on morphine immunization: "It is possible to obtain in dogs an habituation to large doses of morphine differing from that in man in that the suspension of its administration causes no phenomena of abstinence." 2. The serum of animals so treated possesses an antitoxic, therapeutic, and preventive action against morphine poisoning, even when the subjects of experiments are animals very susceptible to the action of the drug, such as chickens. 3. The antitoxic properties of the serum are not due to the presence of excreted morphine since between the excreted morphine and its ex-

only an incomplete nosographic antagonism from which no benefit can be derived in poisoning by these alkaloids. 4. Morphine in contact with antimorphinic serum does not undergo any modification either permanent, physical, chemical, or biological; so that it is not possible to interpret the antitoxic action of the serum as a fact of an exclusively chemical order.

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, and cholera were reported to the supervising surgeon-general of the United States Marine-Hospital Service during the week ending January 7, 1899:

Small-pox—United States.

Detroit, Mich.	Jan. 1.	4 cases.
Minneapolis, Minn.	Dec. 8.	1 case.
Chandler, Oklahoma	Dec. 30.	1 "
Daggett, Oklahoma	Dec. 30.	1 "
Parkland, Oklahoma	Dec. 30.	1 "
Saes and Fox Agency, Oklahoma.	Dec. 30.	1 "
Stroud, Oklahoma	Dec. 30.	1 case.
Ball Hill, Pa.	Dec. 31.	1 "
Charlottesville, Pa.	Dec. 31.	Small-pox suspected.
East Vincent Township, Pa.	Dec. 31.	1 case.
Everett, Pa.	Dec. 31.	5 cases.
Homer City, Pa.	Dec. 31.	2 "
Hopewell, Pa.	Dec. 31.	4 "
Houstonville, Pa.	Dec. 31.	7 "
New Granada, Pa.	Dec. 31.	1 case.
Pittsburgh, Pa.	Dec. 31.	1 "
Steelton, Pa.	Dec. 31.	11 cases.
Waterfall, Pa.	Dec. 31.	1 case.
Alexandria, Va.	Jan. 4.	8 cases.
Newport News, Va.	Dec. 31.	4 "
Norfolk, Va.	Dec. 31.	10 "
Rock Springs, Wyoming.	Dec. 24.	1 case.

Small-pox—Foreign.

Lorenzo Marques, Delagoa Bay, Africa.	May 1-31.	5 deaths.

Mushroom Juice as an Antitoxine against Serpent Venom. The Paris correspondent of the *Lancet* for December 24th says that M. Phisalix gave the result of some experiments which he had made on the use of mushroom juice as an antitoxine against serpent venom at the meeting of the Academy of Sciences held on December 12th. He first of all pointed out that tyrosine, which is the chemical nucleus of all albuminous bodies, when extracted from the juice of serpent, has an immense power against their venom. He said that he had been led to seek whether the juice of mushroom, which contains

plenty of tyrosine and some ferments as well, would not possess the same properties. He made various experiments and found out that all kinds of mushrooms possess a substance which acts as an antitoxine against serpent venom. If, for instance, the juice of the ordinary hot-bed mushroom is extracted by pressure or by maceration in water and inoculated into a guinea-pig, the animal is rendered absolutely refractory to serpent venom. Unfortunately, however, the inoculation seems to possess toxic properties which vary in degree according to the size of the dose. In the rabbit, for instance, the injection of twenty-five cubic centimetres of mushroom juice is fatal, the animal dying from intervascular coagulation. With a view to avoiding these results M. Phisalix tried filtering and boiling the juice, but all the same the toxic properties remained, although they were much diminished.

What's in a Name?—We have read in some paper, which we do not recollect, of a young lady who went into a bookstore and asked for a copy of *Appendicitis*. "What is the author's name, Miss?" asked the clerk. "Thackeray," replied the fair purchaser. Whereupon the clerk brought her *Pendennis*. And he was right.

Partial Excision of the Urethra.—Dr. S. Baumgarten (*Centralblatt für die Krankheiten der Harn- und Sexual-Organen*, 1898, vol. ix, p. 119; *Annales des maladies des organes génito-urinaires*, December, 1898) reports the case of a man, thirty-three years of age, who had had gonorrhoea six years previously, and who presented himself with a stricture of the urethra, which permitted the passage of only a filiform bougie. The stricture, which was very dense, was progressively dilated until a No. 13 bougie (French scale) could be passed. Exploration of the bladder discovered the presence of an elongated calculus. As the dilatation made no further progress, perineal section was performed, the calculus extracted, and the strictured portion of the urethra was excised. A cure without any complications followed.

The American Breakfast.—Dr. Boardman Reed (*Journal of the American Medical Association*, December 21th; *Philadelphia Medical Journal*, December 31st) believes that the American breakfast is most irrational and is one of the factors responsible for the prevalence of dyspepsia, the ice-water habit being another, and rapid eating a third. He believes in the frugal Continental method of breaking fast, but if a large meal is eaten in the morning, it should, with a view of favoring the starch digestion, be arranged as follows: (1) Cereals well masticated, and accompanied by rolls or bread and butter to carry down plenty of saliva; (2) potatoes with more bread and butter if desired; (3) meat or eggs, accompanied by a little salad; (4) fruit; (5) coffee or chocolate. Ice water retards digestion, both by lowering the temperature of the contents of the stomach and by an overdilution of the gastric juice; it may also damage the mucous membrane and lead, ultimately, to catarrhal inflammation in persons otherwise predisposed to that affection.

Silence at the Operation Table.—Hubener (*Zeitschrift für Hygiene und Infektionskrankheiten*, 1898, vol. xxviii, No. 3; *Presse médicale*, December 7th) has made a series of experiments to ascertain the part played by the mouths of those about the operating table in producing wound contamination. On an operating table he disposed crosswise four Petri dishes. Then, having

rinsed his mouth with a culture of *Bacillus prodigiosus*, he stationed himself about twenty inches from the nearest plate and for ten minutes spoke, sometimes in an ordinary voice, sometimes in a low, and sometimes in a high one.

In every case, and especially when he had spoken in a high voice, cultures of the bacillus developed in the Petri plates, being particularly abundant in those plates nearest to him. Similar experiments conducted by speaking through a mask similar to an Esmarch's chloroform inhaler containing a layer of absorbent cotton left the plates sterile.

Bacilli in Hailstones.—According to the *Druggist's Circular and Chemical Gazette* for December, quoting the *Botanical Gazette*, F. C. Harrison has examined hailstones bacteriologically and obtained cultures of *Penicillium glaucum*, *Mucor* sp. [sic], *Aspergillus* sp. [sic], *Bacillus fluorescens liquefaciens*, a protean form of *Proteus vulgaris*, and a bacillus and a coccus apparently hitherto unknown, for which he proposed the names of *Bacillus flavus grandinis* and *Micrococcus mollius grandinis*.

The Association of the Alumni of Mount Sinai Hospital will hold its next meeting at the Arena, No. 39 West Thirty-first Street (telephone, 1056-38), on Monday, January 16th, at 8.30 p. M. The paper of the evening will be entitled Experiences in the Gynecological Service of Mount Sinai Hospital, by Dr. P. F. Munde.

The Buffalo Academy of Medicine.—At the last regular meeting of the Section in Medicine, on Tuesday evening, the 10th inst., the following papers were presented for discussion: Auto-intoxication, by Dr. A. W. Hurd; Membranous Enteritis as found in Nervous Diseases and Insanity, by Dr. H. A. Wood; The Relation between Physical and Mental Diseases, by Dr. H. P. Frost; A Few Notes on Paralysis, by Dr. H. Kuhlman; and Notes of Cases, by C. J. Patterson.

The Mount Sinai Hospital.—Dr. Max Rosenberg has been appointed as admitting physician to Mount Sinai Hospital.

Changes of Address.—Dr. Edwin R. Chadbourne, to Pasadena, California. Dr. W. J. Copeland, from Elmira, N. Y., to Hornellsville, N. Y.

Marine-Hospital Service.—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending January 5, 1899:

PETTUS, W. J., Passed Assistant Surgeon. To proceed to Norfolk and Newport News, Va., for special temporary duty. January 3, 1899.

PERRY, J. C., Passed Assistant Surgeon. Relieved from duty at Port Townsend, Wash., to take effect with the arrival of GARDNER, C. H., Passed Assistant Surgeon, and to retain command of the Port Townsend Quarantine Station. January 3, 1899.

STEWART, W. J. S., Passed Assistant Surgeon. To proceed to Alexandria, Va., and Hamlet, Md., for special temporary duty. December 31, 1898. Relieved from duty at bureau and directed to proceed to Vineyard Haven, Mass., and assume command of service. January 3, 1899.

GARDNER, C. H., Passed Assistant Surgeon. To proceed, relieved from duty at Baltimore, Md., to proceed to

Port Townsend, Wash., and assume command of service. January 3, 1899.

TABB, S. R., Assistant Surgeon. Upon being relieved from duty at Vineyard Haven, Mass., and upon expiration of leave of absence granted by bureau letter of November 29, 1898, to proceed to Baltimore, Md., and report to medical officer in command for duty and assignment to quarters. January 3, 1899.

HOLZENDORF, B. E., Hospital Steward. Granted two days' extension of leave of absence. December 30, 1898.

Appointments.

CHARLTON, CHARLES G., of South Dakota, to be junior hospital steward. December 30, 1898.

SOUTHARD, FRANK A., of Indiana, to be junior hospital steward. December 30, 1898.

PURIFOY, JOHN, Jr., of Alabama, to be junior hospital steward. December 30, 1898.

Society Meetings for the Coming Week:

MONDAY, January 16th: New York Academy of Medicine (Section in Ophthalmology and Otolaryngology); New York County Medical Association; Hartford, Connecticut, Medical Society; Chicago Medical Society.

TUESDAY, January 17th: New York Academy of Medicine (Section in General Medicine); Buffalo Academy of Medicine (Section in Pathology); Ogdensburg, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Societies of the Counties of Kings (annual) and Oswego (semi-annual—Cooperstown), N. Y.; Connecticut River Valley Medical Association (Bellows Falls), Vermont; Baltimore Academy of Medicine.

WEDNESDAY, January 18th: Medico-legal Society, New York; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society.

THURSDAY, January 19th: New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Massachusetts, Society for Medical Improvement (private); Medical Society of City Hospital Alumni of St. Louis; Atlanta Society of Medicine.

FRIDAY, January 20th: New York Academy of Medicine (Section in Orthopaedic Surgery); Clinical Society of the New York Post-graduate Medical School and Hospital; Baltimore Clinical Society; Chicago Gynecological Society.

Births, Marriages, and Deaths.

Marriages.

HUMPHREY, THOMAS, D. D., 4th, on Wednesday, Jan. 13, 1899, Dr. J. C. Humphrey, of Saratoga Springs, N. Y., and Miss M. C. Thompson, of New York City.

JANSEN, GEORGE, D. D., 1st, on Wednesday, Jan. 12, 1899, Dr. J. C. Jansen, of Florida, N. Y., and Miss Sarah B. C.

MURRAY, MARGARET, D. D., 1st, on Tuesday, January 11, 1899, Dr. J. C. Murray, of Worcester, Mass., and Miss M. C. Murray, of New York City.

WALKER, JOHN, D. D., 1st, on Wednesday, January 12, 1899, Dr. J. C. Walker, of New York City, and Miss M. C. Walker, of New York City.

Died.

CHESEBRO.—In Providence, Rhode Island, on Saturday, January 7th, Edmund Denison, Jr., son of Dr. Edmund D. Chesebro.

CLEVELAND.—In Spartanburg, South Carolina, on Wednesday, January 4th, Caro Virginia Cleveland, wife of Dr. Jesse F. Cleveland.

HOYT.—In Canandaigua, N. Y., on Tuesday, December 13th, Dr. Charles S. Hoyt, in the seventy-sixth year of his age.

HUZZA.—In New York, on Friday, December 9th, Dr. Thomas H. Huzza, of Atlanta, Georgia, aged thirty-five years.

LE ROUX.—In New Orleans, on Tuesday, December 27th, Dr. Charles Louis Le Roux, of Pass Christian, Mississippi, in the fifty-third year of his age.

MCMAHUS.—In New York, on Thursday, January 5th, Dr. Charles W. McMahus, aged twenty-two years.

NICOLL.—In Shelter Island, N. Y., on Wednesday, January 4th, Dr. Samuel B. Nicoll, in the seventy-fourth year of his age.

NOTT.—In Union, South Carolina, on Wednesday, January 4th, Dr. William B. Nott, son of Dr. Thomas E. Nott, of Spartanburg, South Carolina.

ROCHON.—In Glens Falls, N. Y., on Friday, January 6th, Dr. Charles A. Rochon, in the thirty-seventh year of his age.

RODGERS.—In Bennington, Vermont, on Wednesday, January 4th, Mary D. Rodgers, wife of Dr. Lyman Rodgers.

SHARER.—In Little Falls, N. Y., on Sunday, January 8th, Dr. John P. Sharer, in the seventy-fifth year of his age.

STILLMAN.—In Andover, N. Y., on Monday, December 5th, Dr. Edwin M. Stillman.

TAYLOR.—In New York, on Saturday, January 7th, Elizabeth M. Taylor, wife of Dr. Robert W. Taylor.

WEBSTER.—In Troy, N. Y., on Friday, January 6th, Dr. Stephen Henry Webster, in the thirty-fifth year of his age.

WHITE.—In Utica, Mississippi, on Saturday, December 31st, Dr. A. S. White, in the thirty-second year of his age.

Letters to the Editor.

THE LAPLACE INTESTINAL-ANASTOMOSIS FORCEPS.

1828 SOUTH RITTENHOUSE SQUARE,
PHILADELPHIA, January 9, 1899.

To the Editor of the *New York Medical Journal*:

SIR: In last week's issue of your journal, Dr. Genella, while describing a modification of my clamps for intestinal anastomosis, says that his "instrument is superior to Dr. Laplace's modification of Dr. Murphy's," etc.

I wish to state that the description of my forceps, as presented to the American Medical Association at Denver last June, and described in the *Philadelphia Medical Journal* for June 9, 1898, and in the *Philadelphia Polyclinic* for December 3, 1898, shows no resemblance to the Murphy button, and is in no way a modification of that device.

Furthermore, the device presented by Dr. Genella is identical with one which on November 23, 1898, at the meeting of the Philadelphia County Medical Society, I

stated that I had discarded over a year before, as not having all the necessary qualities, which are possessed by my new forceps, for lateral as well as end-to-end anastomosis (*Philadelphia Polyclinic*, December 3, 1898).

ERNEST LAPLACE, M. D.

ALCOHOL AS AN ANTIDOTE FOR EXTERNAL CARBOLIC-ACID POISONING.

25 WEST THIRTY-FOURTH STREET,
NEW YORK, January 7, 1899.

To the Editor of the *New York Medical Journal*:

SIR: My attention has been directed to the subject of carbolic acid by an article which appears in the *New York Medical Journal* for this date, by Bernard Weiss, M. D., who reports a case of local poisoning with pure carbolic acid injected into the vagina with a fountain syringe, the patient having put pure carbolic acid into water after it had been introduced into the fountain bag. He treated the case with sodium-sulphate solution. This sodium sulphate forms with carbolic acid a sulphocarbonate of sodium, and neutralizes the effect of carbolic acid. Dr. Weiss also states that "this chemical antidote even Wittlaus fails to mention in his *Chemistry*."

No doubt sodium sulphate does exercise a soothing effect in local carbolic-acid poisoning, but it will not prevent the blistering or the deep escharotic effect of carbolic acid when applied pure to the tissues. For this reason and because the profession needs an antidote that will at once neutralize the effect of carbolic acid, and render it in a moment's time perfectly inert, no matter how or to what tissues applied, I present this communication.

Dr. Seneca D. Powell, of New York, has for a long time used in his clinics at the Post-graduate Hospital an antidote that we have all come to recognize as a specific. I allude to alcohol, and it is not an unusual occurrence to see Dr. Powell, in the presence of the class, catch in his open hands a quantity of pure carbolic acid poured into them by a nurse from a bottle. In a few moments the doctor puts his hands into a basin of pure alcohol, and no escharotic effect is observed whatever from the action of the carbolic acid upon the skin. I was somewhat surprised when I saw this first experiment, but when I recognized the result I was convinced of the scientific fact. At the present time we are flushing out abscess cavities with pure carbolic acid and washing them out a few moments later with pure alcohol. In empyema Dr. Powell, after making a large opening in the chest wall, washes out the cavity with a ten-per-cent. solution of carbolic acid, after which pure alcohol is used, and no bad effect has thus far been observed from this treatment. The cavity of the pleura is rendered aseptic. From personal observations and demonstrations in the use of pure carbolic acid followed by the use of alcohol, I can state to the profession positively that we have in alcohol an absolutely safe and sure specific against the escharotic action of pure carbolic acid. And I believe that this fact should be given wide publication to the profession and even to the laity, because in cases of carbolic-acid poisoning with homicidal intent, if, immediately after the administration of the poison, alcohol was thrown into the stomach of the individual, the poisonous effect of carbolic acid would be at once neutralized. However, as to the subsequent constitutional effect from the absorption of the new compound formed I can not speak, but certainly in all cases of local

carbolic-acid poisoning, particularly in such a case as that mentioned by Dr. Weiss, I have found that alcohol is an absolute, powerful, and immediate specific.

A. M. PHELPS, M. D.

THE AMERICAN GYNÆCOLOGICAL SOCIETY AND ANTISTREPTOCOCCUS SERUM.

2945 GROVELAND AVENUE, CHICAGO, December 31, 1898.

To the Editor of the *New York Medical Journal*:

SIR: In your issue for December 3, 1898, there appears a letter from Dr. Pryor, of New York, in regard to the work of the committee appointed by the American Gynæcological Society to investigate and report upon the efficacy of antistreptococci serum at the next annual meeting of that society. In this communication it is stated that the committee recommends the use of the serum prepared by the New York board of health, and furthermore, that it is "manifestly desirable that one kind of serum be employed in all cases," etc.

To many physicians throughout the United States who have had more or less experience in the use of blood serums it will doubtless be difficult to comprehend the "manifest" desirability above mentioned, and also why discrimination should be made in favor of the serum prepared by the New York board of health. This discrimination seems particularly puzzling from the fact that boards of health are not generally known as manufacturers; and the one in question has been repeatedly and unmercifully scored by both the medical and lay press, as well as by hundreds of physicians, for engaging in a commercial venture which "manifestly" does not come within its legitimate province. Furthermore, I am assured by one connected with this board that, so far as the antistreptococci serum is concerned, only a limited quantity of it has been distributed among the physicians of New York, and none of it has been permitted to pass beyond the confines of that city. If this is true it necessarily follows that the serum's reputation as a "standard" product depends very largely upon what the New York board of health says about it, and the faith with which it is expected to be gulped down by the profession at large. Very few serums become "standard" before they are known outside of the laboratory where they are prepared.

To the intelligent readers of the *Journal*—which includes the entire list—it is well known that there are several American manufacturers of serums—known and recognized as such—whose products are as easily obtainable in New York as the one recommended by the committee; and it seems a great injustice to these manufacturers that their serums are not accorded equal recognition by the committee in order that comparisons might be made as to their relative merits.

If but a single make of domestic serum is to be used in this investigation, the results obtained can only be conclusive as to the merits of that particular brand; and although the committee may have reasons for dubbing it a standard preparation, those reasons have not been given to a more or less skeptical public. Not only this, but every physician of experience is fully aware of the wide variation that exists among "standard" products as to quality, strength, purity, and therapeutic activity. This variation is more noticeable in antitoxines and blood serums than in any other class of remedial agents for the simple reason that the art of preparing them is so new and so complex that very few manufacturers have had the necessary experience to enable them to prepare

a perfect or even a reliably "standard" product. This fact was beautifully demonstrated in the competitive tests that were made some time ago with diphtheria antitoxines, when many of the serums fell far short of their pretended strength, and a few were so weak as to be absolutely worthless.

The antistreptococci serum is admittedly one of the most difficult of its class to manufacture; it is the one above all others which is in the balance of public estimation; its immediate fate, at least in the United States, depends very largely upon the report of the investigating committee; and in order that this report may be convincing, and at the same time just and impartial, it seems to me that there are just two ways in which the work can be done. One would be for the committee to recommend the use of the serums of all of the principal manufacturers and let each one stand or fall by its own merits. The other would be, if the committee persists in its "close communion" method, to recommend the use of a serum which is not only "standard," but which is everywhere known, received, and acknowledged as the most excellent of its kind. Of course, I refer to the serum prepared by Dr. Marmorek himself, whose name is as intimately associated with antistreptococci serum as is that of Pasteur with the hydrophobia cure.

In all probability the rank and file of the profession would prefer a report based upon a trial of serums prepared by the various manufacturers; but, being denied this, it is equally probable that a feeling of doubt will remain long after the report has been filed unless the serum used in the investigation shall be that of its originator, Dr. Marmorek, of the Paris Pasteur Institute. "Marmorek's serum" and "antistreptococci serum" are regarded as synonymous terms by a large proportion of the medical profession; and if Marmorek's own preparation is used in the tests to be made, the results will be regarded as conclusive as to the merits of *antistreptococci serum*—and this will not be true if a single serum of any other make is used.

If the present programme is adhered to it will be necessary for the Gynæcological Society to appoint a committee for each manufacturer before final definite conclusions can be reached; and, aside from the great labor and long wait incident to such a course, a great many valuable lives will probably be sacrificed by failure to make timely use of the Marmorek serum in cases of streptococcal infection.

It is to be hoped that the opinions here expressed will not be construed as a reflection upon the New York board of health, whose earnestness and ability as a health board are gladly acknowledged; nor as an attempt at meddling interference with the work of the committee; but will be taken simply as a Western side-light upon a question of vital importance to the profession and the people of the whole country.

GEOFFREY W. COX, M. D.

BLOOD PARASITES OF FROGS.

1 WEST FRANKLIN STREET, BALTIMORE, January 9, 1899.

To the Editor of the *New York Medical Journal*:

SIR: Dr. Langmann's paper on haemosporidia in your issue of last week reminds me of studies on the subject now many years ago. In 1882 (*Clinical and Veterinary*, vol. X, No. 7) I described and figured the trypomastoma and the dropidid, which were very abundant in the blood of the frog in my laboratory. I think other records exist of the presence of the frog in the country.

try; at any rate they are more generally recognized by instructors in histology than the statement in Dr. Langmann's paper would indicate.

WILLIAM OSLER, M. D.

Proceedings of Societies.

SOCIETY OF THE ALUMNI OF THE CITY (CHARITY) HOSPITAL.

Meeting of October 12, 1898.

The President, Dr. WALTER B. JOHNSON, in the Chair.

A Case of Acute Glaucoma.—Dr. HENRY T. OPPENHEIMER reported the following case of glaucoma of the left eye: The patient was a native of Holland, fifty-three years of age. He had always had good health and good eyesight, and he had felt no pain or discomfort in his eyes until three months ago, when he had felt a terrible pain in the left eye, so intense that he had not been able to sleep for five nights. The eye was red and swollen and had remained so for two months. After that it had gradually improved until it had reached its present condition.

It had been shown, on palpation, that the tension of the left eye was much greater than that of the right eye, and it had felt like a marble under the fingers. The veins on the surface of the sclera were well marked, which was not the case in the healthy eye. The pupil

and restored vision. In this case the conditions were different; the optic nerve had been permanently injured from pressure, and it was doubtful whether an iridectomy would have given any good result. At the time he had seen the patient the pupil was enlarged by atropine, which had been administered by some irresponsible person, and the symptoms had been much aggravated by it. He had used eserine to relieve these symptoms, and if this remedy would lower the tension he would continue to use it and not resort to operation. He presented the case not because of its rarity, but to call attention to the necessity of an accurate diagnosis being made, so as to avoid the mistake of using atropine, which was fatal to a glaucomatous eye, as it immediately increased the tension.

Fibrocyst of the Uterus removed by Abdominal Hysterectomy.—Dr. BROOKS H. WELLS presented the following case: The patient was an unmarried Irish-American, thirty-two years old. She had always had good health, and had first menstruated at the age of fourteen years and a half, and menstruation had been regular and normal. When she was fifteen years old the abdomen was large and hard, and she had been scolded by her mother for "carrying her stomach so high." At this time she had first worn corsets, and had experienced some difficulty in making them fit comfortably over the abdomen. As there had been no pain and she had apparently been well, her condition had attracted no further notice, but the abdomen had always remained prominent.

In May, 1898, she had struck the right side of the abdomen against the corner of a piece of furniture. The blow had been a hard one and had been followed by severe pain, nausea, vomiting, and dizziness. Afterward the abdomen had grown larger and the patient had had continually more or less discomfort, with soreness and throbbing. In July, 1898, Dr. Wells had been asked to examine her, which he had done on the 21st. At that time the abdomen had measured forty inches in circumference and had contained a tense, thin-walled, fluctuating, immovable, rounded tumor which had extended above the umbilicus and had been somewhat more prominent on the right side. The tumor had not been tender and the fluctuating had been very marked. As the patient had objected to a vaginal examination, it had not been made. It had seemed to Dr. Wells that he had to deal with a multilocular cyst of the right ovary, and he had advised its removal by abdominal section.

On September 19th, while sitting, the patient had reached over to pick up a child and had been seized with a sudden and violent pain over the entire abdomen, which had been followed by symptoms of shock. On the 21st the speaker had found her face pale, drawn, and anxious, the pulse about 96 and of high tension, and the abdomen tender, tense, and tympanitic above the tumor. Apprehending rupture of a loculus of the cyst or a twist of its pedicle, he advised an immediate operation, and on the morning of the 26th the abdomen was opened and about three pints of a greenish-brown viscid fluid were found, which had evidently come from the ruptured cyst. Posteriorly and filling the pelvis hard masses of a pinkish-yellow color were found adherent to the sigmoid and upper rectum by dense and very vascular adhesions. When these had

was wider than normal and much longer than that of its fellow. The anterior chamber was shallow and the iris less bright than that of the right eye. The ophthalmoscope had shown the typical cupped appearance of the optic disc with the blood-vessels bending over the edge of the cup and disappearing in its depths. The veins were large, and the arteries pulsed when the slightest pressure was made upon the eyeball.

This was a typical picture of a glaucomatous eye, especially when considered together with the narrowed visual field, as shown in the accompanying chart. The contraction upward and inward was quite characteristic of glaucoma. Dr. Oppenheimer said that if the patient had sought treatment in the beginning of the attack, which was doubtless one of acute glaucoma, he would have done an iridectomy. In acute glaucoma this was the step necessarily indicated, and in the great majority of cases if this was done promptly it checked the attack

been tied off so that the tumor could be lifted up from the abdomen, it was realized that there was a cystic uterus to deal with, and it was removed by a supravaginal amputation. The peritoneal flaps were closed, the abdomen was flushed with sterile normal salt solution and closed, and the patient was put to bed in good condition. Aside from troublesome nausea for thirty-six hours, convalescence had been uneventful. The pulse before the operation had been 84; immediately after, 96; and since then had ranged from 72 to 80. The temperature for the first eight days had ranged between 99° in the morning and from 100° to 101° F. in the evening; after that it had become normal.

Dr. Wells thought that the tumor presented certain peculiarities of interest. When fresh and distended it was of about the size of an adult head; its anterior and superior walls were from an eighth of an inch to a quarter of an inch in thickness; it was of a greenish color, and very soft and friable. The rupture was about two inches and a half in length on the superior surface. The contents were the greenish fluid, already mentioned, and masses of coagulated fibrin. The posterior and inferior walls were thicker, finely nodular, pinkish-yellow, friable, and cheesy in appearance, and were covered with dilated blood-vessels. This appearance was more like sarcoma than fibroid, and had led to a suspicion of malignant degeneration. The microscope, however, had shown it to be a fibroma broken down and in advanced granular degeneration. There had been no histological lining to the cyst walls; it was merely a cavity in a distended mass of myofibromatous tissue.

There were several points of interest to be noted, Dr. Wells thought: Fibroid was very rare in young girls, and in this case there was a history that pointed very strongly to its presence since the age of fifteen. The cause of the cystic degeneration seemed clearly to have been an apoplexy into the interior of the tumor followed by liquefaction of the blood clot and by further degeneration of the tumor walls, until, finally, rupture had occurred. The contents of the cyst had been retained in the abdominal cavity for six days without serious peritoneal irritation. In performing the hysterectomy one ovary had been allowed to remain in order to avert the symptoms attending the artificial menopause. The diagnosis was often, as in this case, obscure, and the growth was usually thought to be a multilocular ovarian cyst until an operation disclosed its true character.

Practical Points in Percentage Feeding.—Dr. WILLIAM L. BAKER read a paper on this subject. (See page 41.)

Book Notices.

A Text-book of Pathology. By ALFRED STENGEL, M. D., Instructor in Clinical Medicine in the University of Pennsylvania, Professor of Clinical Medicine in the Woman's Medical College, Philadelphia, etc. With Three Hundred and Seventy-two Illustrations. Philadelphia: W. B. Saunders, 1898. Pp. 15-818. [Price, \$1.]

COMPLETE text-books on pathology are very novel additions to American medical literature, and the appearance of an entirely new work of comprehensive scope is likely to attract more attention than the publication of a similar treatise on any other branch of medicine.

The first natural inquiry relates to the position which this new treatise aims to secure among similar or related works. Among exactly similar works there are apparently none with which the present volume may be associated. The author has avowedly been guided in his production by the point of view of the clinical pathologist—that is, of the well-read clinician—and has aimed to compile a work with special reference to the needs of the clinician. There are perhaps two main features of the text which are the outcome of this purpose, and which represent probably the chief and special value of this text-book. They are the prominence given to pathological physiology and the separate consideration of the early and late stages of many important lesions. Rather more of the facts of clinical medicine appears also in the discussions of the etiology of disease than is found in many standard works on pathology. Each of these features tends to make the volume especially suitable to the needs of students, and particularly valuable for their instruction. In fact, the author states that the completed work is the outgrowth of lectures prepared for the special instruction of students.

In this domain the author may be congratulated on having produced a very creditable treatise, the compilation of which is a most comprehensive undertaking.

Deserving of special mention is the excellent series of illustrations with which the pages abound. Many of these appear for the first time in a text-book, and the others have been chosen with excellent care and evidently from a sufficiently wide acquaintance with pathological literature.

In another field, in which the supply of text-books produced in English is very limited, the present treatise can not be said to enter into competition with several established works. It is not sufficiently complete or critical to serve as a text-book for general reference, although the intention of the author in this respect is not always clear. What disease usually does, is stated explicitly, but less attention is given to what disease may very often do. A single example may suffice to illustrate the difference in this respect between the present work and a treatise like that of Birch-Hirschfeld or Ziegler. In the paragraph on lymphadenoma of the spleen, the histological changes are described as similar in leucæmia and in pseudo-leucæmia. Yet they may be different in the one disease from the other, or in different cases of the same disease. The splenic enlargement is attributed to hyperplasia of the Malpighian bodies. Yet it may affect the pulp tissue exclusively. Similar comparisons appear throughout the volume, not detracting from its value in a special field, but indicating the natural limitations of a work of this size and character.

Dr. Stengel's treatise should secure recognition, therefore, as a text-book specially adapted to the needs of students and clinicians, but it can not be classed with the original and exhaustive text-books on pathology which represent the best work of modern German, French, and English-speaking pathologists.

Untersuchungen über den Einfluss der Ernährung auf die Histologie der Leber. Von Dr. ALFRED BAYES, Professor der pathologischen Anatomie und Bakteriologie an der Universität zu Bonn. Mit 111 Abbildungen im Text und 18 in der Tafel. Berlin: Springer, 1898. Pp. 111.

THE present work of the author is a monograph on the *Reichs-leber*, and the influence of the various conditions with

which Babes has enriched the literature of the subject, is due to the fact that he was unable, owing to want of space, etc., to treat of them *in extenso* at the lepra conference held in Berlin in 1897. Fortunately was this the case, since to it we owe this valuable treatise, representing the individual work and investigation of the author into every tissue implicated by leprosy.

Beginning with our histological knowledge prior to the discovery of the bacillus, he sketches the investigations of the more prominent leprologists—Virchow, Thoma, Danielssen, and Boeck—and he then takes up the subject of the bacillus, entering into its forms, its staining qualities, and the attempts at cultivating it which have been made. The question of the mode of entrance of the bacillus into the tissues is carefully considered, as well as its cellular site, and then the histological features of leprosy of the skin, eye, larynx, nervous system, genital organs, glands, lungs, digestive tract, etc., receive thorough treatment in separate chapters.

Babes recognizes that the bacillus is the important cause of the symptoms characterizing leprosy, and thinks that the cases in which it is not found are explained by an error in diagnosis or by the fact that the point where they were situated was not examined. He states that the lepra bacillus in its more minute structure is very similar to the tubercle bacillus, but yet distinguishable from it by its reaction to dyes, etc. Especially is the difference between the two shown by the fact that incontestable pure cultures of lepra bacilli and successful inoculations on animals have not yet been made. Babes states that his demonstration of the bacilli on the surface of the skin and in the hair sacs, in the various secretions, and in pus from ulcerations, suggests the possibility of contagion from contact, but yet other conditions are probably necessary. After considering all sides of the question, Babes concludes, however, that it is not possible to determine the paths by which the bacillus penetrates into the system.

These few references to the contents of the monograph are certainly sufficient to show the valuable material which it contains. It should be read eagerly by everybody interested in leprosy from the scientific point of view. A spirit of judicial fairness pervades the book, and one feels that it is the work of an earnest seeker after scientific truth, and not of a bidder for transient notoriety. The illustrations accompanying the publication and demonstrating histological preparations are exquisite. They make one regret deeply that, whether it is on account of the cost or for some other reason, such work can not be done in this country, or at any rate is not.

Ueber Malaria- und andere Blutparasiten nebst Anhang.

Eine wirkliche Methode der Chromatin- und Blutfärbung. Von Dr. HANS ZIEMANN, Marinestabsarzt. Mit 165 farbigen Abbildungen und Photogrammen auf 5 Tafeln und 19 Eideckkurven. Jena: Gustav Fischer, 1898. Pp. v+192.

THIS monograph presents the results of the author's studies of the parasitology of two hundred and fifty-four cases of malarial disease occurring in western Africa, Italy, and Germany, and of the related blood-parasites found in tropical animals, principally birds, and in cattle suffering from "Texas fever." The monograph deserves to rank among the most important of recent contributions to this subject. Its conclusions are based upon a minute study of the morphology of the parasites as demonstrated by a modification of Roman-

novsky's staining method devised by the author. Ziemann's staining fluid is prepared by adding a one-per-cent. watery solution of cosine to a one-per-cent. watery solution of methylene blue, in proportions which vary with the specimens, the age of the solutions, and some other inconstant factors. The results of the method, while very effective in some instances, are so unreliable even in the author's own hands that it is probable that Ziemann will have a monopoly in the use of his method until he can give a more accurate and intelligible description of the technics. Granting that some one else can learn to apply the method successfully in order to verify his results, and granting that his interpretation of the structures demonstrated is correct, Ziemann's conclusions are of interest and importance.

Ziemann has found the æstivo-autumnal parasite in a case of quartan fever, the first recorded instance. His method demonstrates especially the chromatin of the parasite, and he finds in the behavior of the chromatin essential differences in the quartan, tertian, and æstivo-autumnal parasites. He gives three important characteristics which serve to distinguish sterile from fertile parasites. Sterile parasites tend to increase in size; they lose their amœboid motion, although the pigment may show active molecular vibration; and the pigment of sterile forms is superabundant and very coarse-grained.

With the data secured by means of his staining method the author enters into the critical discussion of the parasitology of malaria, and professes to have settled many hitherto obscure points. Whether Ziemann's conclusions are correct or not, his contribution deserves careful perusal by all interested in the full study of these important diseases.

A Guide to the Clinical Examination of the Blood for Diagnostic Purposes. By RICHARD C. CABOT, M. D.

With Colored Plates and Engravings. Third Revised Edition. New York: William Wood & Co., 1898. Pp. xliii+4 to 440.

As compared with the first edition, this work has now received extensive additions and alterations, and is considerably improved in all departments.

The conspicuous additions are a chapter on the serum reaction in typhoid fever, and descriptions of Oliver's tintometer and hemoglobinometer, Müller's blood dust, special tests for diabetic blood, the iodine reaction in suppurative processes, and the changes in the blood of several minor infectious diseases and in various forms of acute poisoning. Less prominent but equally valuable additions to the treatment of the subject of primary and secondary anemias will also be found.

Several photomicrographs are a distinct addition to the illustrations of the work, in which it is still somewhat deficient.

The present volume more than ever furnishes the most exhaustive report of clinical blood examination that has yet appeared in any language. However, no other writer has ever attempted to write just such a work, so that it can not be fairly compared with the more critical works on the clinical pathology of the blood. The writer says he has eliminated what little theoretical discussion existed in previous editions. This would be a matter of regret were it entirely true, but it appears that in some particulars rather more critical

thought has been devoted to certain subjects, to the great advantage of the reader. Critical theoretical discussion is just what the work has always needed in order to make it something more than a compilation, and a real "guide" to the less experienced worker.

The numerous tables of routine blood examinations require condensation and analysis to be of great value, and it does not appear necessary to keep such a book fully abreast with all that is being written on the blood, for much of this is error. It would have been better to omit all mention, for instance, of Neusser's "perinuclear basophilia," described and properly interpreted by Löwit years before Neusser's description appeared. A criticism of the present work often mentioned is a failure to discriminate between authorities, the experienced and the inexperienced being cited often with equal prominence. In a field in which the literature abounds in reports, theories, and conclusions, based on incompetent evidence, it is a function of first importance to guide the reader aright by a careful critical estimate of authorities. It would appear, therefore, that considerable theoretical discussion is required in any work on the blood, especially if it is to stand as a finished scientific production.

BOOKS, ETC., RECEIVED.

A Manual of Physiology. With Practical Exercises. By G. N. Stewart, M. A., D. Sc., M. D. (Edin.), D. P. H. (Camb.), Professor of Physiology in the Western Reserve University, Cleveland, etc. With Numerous Illustrations, including Five Colored Plates. Third Edition. Philadelphia: W. B. Saunders, 1899. Pp. 5 to 848. [Price, \$3.75.]

The Treatment of Wounds: its Principles and Practice, General and Special. By Lewis Stephen Pilcher, A. M., M. D., Late Passed Assistant Surgeon, United States Navy, etc. With One Hundred and Forty-two Wood Engravings. New York: William Wood & Co., 1899. Pp. xiii+453. [Price, \$3.]

Glaucoma: its Symptoms, Varieties, Pathology, and Treatment. By Alexander W. Stirling, M. D., C. M. (Edin.), D. P. H. (Lond.), Late House Surgeon, Royal Westminster Ophthalmic Hospital, etc. With Illustrations from Microphotographs. St. Louis: Jones H. Parker, 1899. Pp. viii+177.

A Syllabus of Materia Medica. Compiled by Warren Coleman, M. D., Instructor in Clinical Medicine and Materia Medica in Cornell University, Medical Department, etc. New York: William Wood & Co., 1899. Pp. vi+169. [Price, \$1.]

The Medical News Pocket Formulary for 1899. By E. Quin Thornton, M. D., Demonstrator of Therapeutics, Pharmacy, and Materia Medica in the Jefferson Medical College, Philadelphia. Philadelphia and New York: Lea Brothers & Co., 1899. Pp. 272. [Price, \$1.50.]

Saunders's Pocket Medical Formulary. With an Appendix containing Posological Table; Formulae and Doses for Hypodermic Medication; Poisons and their Antidotes; Diameters of the Female Pelvis and Fetal Head; Obstetrical Table; Diet List for Various Diseases; Materials and Drugs used in Antiseptic Surgery; Treatment of Asphyxia from Drowning; Surgical Remembrances; Tables of Incompatibles; Eruptive Fevers; Weights and Measures, etc. By William M. Powell, M. D., Member of the Philadelphia Pathological Society, etc. Fifth Edition, thoroughly revised. Philadelphia: W. B. Saunders, 1899. Pp. 290. [Price, \$1.75.]

Das Weib in seiner geschlechtlichen Eigenart. Nach einem in Göttingen gehaltenen Vortrage. Von Dr. Max Runge, ord. Professor der Geburtshilfe u. Gynäkologie, etc. Dritte neubearbeitete Auflage. Berlin: Julius Springer, 1898. Pp. ix+39.

Die Einschränkung des Bauchschnitts durch die vaginale Laparotomie (Kölpoceiotomia anterior). Von Professor Dr. A. Dührssen, in Berlin. Mit 7 Abbildungen und 6 Tabellen. Berlin: S. Karger, 1899. Pp. 266.

Die Fremdkörper des Uterus. Zusammenstellung von 550 Beobachtungen aus der Literatur und Praxis. Von Dr. Franz L. Neugebauer, Vorstand der gynäkologischen Klinik des Evang. Hospitals in Warschau. Zweite Ausgabe. Berlin: S. Karger, 1899. Pp. 144.

Essai de sérumthérapie antituberculeuse (méthode Maragliano). Faits à la clinique médicale de l'Université de Genève. Par le Dr. G. Zanoni. Genève: Paul Dubois, 1898. Pp. 7 to 168.

Die gestielten Anlänge des Ligamentum Latum. Von Doct. Dr. Emil Rosta, in Graz. Mit zwei lithogr. Tafeln. Berlin: S. Karger, 1899. Pp. 54.

New York Charities Directory. A Classified and Descriptive Directory to the Philanthropic, Educational, and Religious Resources of the City of New York, including the Boroughs of Manhattan, the Bronx, Brooklyn, Queens, Richmond. Ninth Edition. New York: The Charity Organization Society, 1899. Pp. xxiv+744. [Price, \$1.]

Transactions of the Royal Academy of Medicine in Ireland. Volume XVI.

The Forty-fifth Annual Report of the New York Infirmary for Women and Children.

The Annual Report of A. H. Doty, Health Officer, Port of New York. For the Year 1897.

The Thirty-first Annual Report of the Managers of the Hudson River State Hospital at Poughkeepsie, N. Y., to the State Commissioner in Lunacy. For the Year ending September 30, 1897.

Report of the Board of Trustees of the Upper Peninsula Hospital for the Insane for the Period ending June 30, 1898.

The Eighth Annual Report of the Eye, Ear, Nose, and Throat Hospital, of New Orleans. January 1, 1897, to December 31, 1897.

Consumption: Cases that should go to Colorado and Cases that should Stay at Home. By George L. Richards, M. D., of Fall River, Massachusetts.

Perichondritis of the Larynx. By George L. Richards, M. D. [Reprinted from the *Philadelphia Medical Journal*.]

Miscellany.

What Shall the Physician say to a Gonorrhœal Patient who wishes to Marry? Kronmayer (*Munchener medizinische Wochenschrift*, No. 24; *International Medical Magazine*, December) sums up the question as follows:

If the presence of Neusser's gonococcus is demonstrated, the physician's duty is clear and needs no elucidation. But, if the bacteriologic examination is negative, his answer should cover the following points:

As a negative bacteriologic examination is not an absolute proof of the absence of gonococci, it is the patient's first duty to make persistent and strenuous effort

to rid himself of the gonorrhœa or chronic inflammation of the urethra by a systematic course of specific treatment. This is not to be neglected even in cases where the examination has for a long time repeatedly failed to detect gonocœci.

If a complete cure is found impossible, or if the patient refuses to subject himself to further treatment, the physician should explain the case under its various aspects, and leave the decision with the patient. In no case is the physician to assume the responsibility of the gonorrhœa not becoming infectious.

If the patient decides to marry, the physician should impress upon him the fact that he is still capable of giving the infection, and must, therefore, observe the following rules in sexual intercourse:

1. Urinate immediately before sexual congress to expel any secretion that may have accumulated in the urethra.

2. Avoid as much as possible having intercourse oftener than once a day.

3. Never perform the act twice in succession, because, if the first seminal discharge contains gonocœci, the friction attending the second coitus brings them into closer contact with the urethra and cervix, thereby increasing the danger of infection.

If this rule is disregarded, and the act is performed more than once in twenty-four hours, the vagina should be thoroughly flushed out with a vaginal douche, which should, in general, be employed as often as possible.

The Toxicity of Appendicular Inflammation.—M. Dienlaffoy (*Revue du praticien*, December 15th) draws at the end of a lengthy paper, presented to the French Academy of Medicine, the following conclusions: 1. The toxicity of appendicular inflammation is confirmed both clinically and by laboratory investigation. 2. This toxicity may be slight, intense, or even mortal. 3. In the more benign and more common form the toxicity displays itself by a subicteric tint with urobilinuria and albuminuria. 4. The icteric tint, indicating affection of the liver, is sometimes significant of an extremely grave intoxication attacking the nervous system and showing itself by symptoms of cerebral, bulbar, or typhoid type. 5. The sole means of warding off attacks of appendicular inflammation is the suppression of the infective focus. 6. Given a correct diagnosis and early operation *secundum artem*, accidents may be warded off. 7. A death from appendicular inflammation ought never to occur.

Gumma of the Tongue without other Specific Symptoms.—Dr. William S. Gottheil (*International Medical Magazine*, December) records the case of Mary H., American, twenty-four years old, who came to his clinic on April 15, 1898, complaining of a sore tongue. Examination showed the presence of a large elongated tumor occupying the central area of the anterior part of the organ, and measuring an inch and a half in length by three quarters of an inch in breadth. The edges and base of the tumor were moderately hard and infiltrated, but there was no characteristic sclerosis. The central part of the tumor was occupied by a ragged, deep, longitudinal ulceration, covered apparently with florid granulation. The submaxillary glands were moderately swollen and quite hard. The tumor had commenced a small lump deep in the tongue eight weeks before, and was steadily getting larger. The exact time at which ulceration had begun could not be determined; in fact, the patient attached very little

importance to that feature of the affection; there was no history of a sudden rupture, as of an abscess. There was absolutely no pain connected with the affection, and the patient complained only of the discomfort and inconvenience caused by the presence of the tumor in her mouth.

No evidences of past or present syphilis were found anywhere, and this, with the age of the patient, her robust health, and the fact that she was a modest girl, had been recently married to an apparently healthy husband, and was pregnant, seemed to exclude tertiary syphilis. No stress was laid upon the history, more especially in the case of a woman; but as a matter of fact that was entirely negative. Cancer could be excluded from her age and sex. Primary tuberculosis was excluded from the appearance and course of the ulceration, and the normal condition of her lungs, larynx, and general system. The diagnosis lay between an ulcerated initial lesion and a softened gumma, with the chances apparently greatly in favor of the former.

The patient was therefore given a placebo and kept under observation. Both the tumor and the ulceration increased slowly but steadily in size. On May 4th the mass had become somewhat softer. It was then the eleventh week after the appearance of the tumor, and not a single secondary manifestation had shown itself. The diagnosis of gumma was then made, and the results of treatment rapidly proved its correctness. Under moderate doses (ninety grains daily) of the iodide of potassium, conjoined with small doses of mercury, the tumor rapidly decreased in size; the ulceration healed up; and three weeks later, when the patient withdrew from observation, there was hardly a trace to be felt in the tongue of the original induration, and the tumefied glands were reduced to one half their former size.

The interesting point in the case, says the author, apart from the comparative rarity of the affection, is the presence of a tertiary lesion in a patient so young and presenting not the slightest evidence of luetic infection. It is an additional argument, if one were needed, of the absolute necessity of making the diagnosis in syphilis, as in ordinary dermal affections, from the objective symptoms alone, and absolutely disregarding the anamnesis.

Antitoxic Relation between Bee Poison and Honey (?).—Dr. G. H. Stover (*Johns Hopkins Hospital Bulletin*, November) says that Miss M., aged thirty-five, single, consulted him on September 9, 1895, on account of the rather unusual swelling of her right cheek following a bee sting received some days before; the whole right side of the face was considerably swollen and she felt some constitutional symptoms. After treatment for five days she recovered, and on her final visit made the interesting statement that, while in the past she had never been able to eat honey and was, indeed, nauseated by even the smell of it, since being stung she had developed a craving for it, and found that she could eat it with complete satisfaction and with no ill results.

The author asks: Will some of the immunization experimenters throw light on this occurrence?

The Indications for the Employment of Hydrochloric Acid in Affections of the Stomach.—In his Lyons thesis of 1898, according to the *International Medical Magazine* for December, Perran says that, although hydrochloric acid is already old as a therapeutic remedy for diseases of the stomach, authors are still far from agreeing on the cases in which it should be em-

ployed, and, above all, as to the quantity of the drug to be employed. Indeed, while certain clinicians prescribe from fifteen to thirty minims per day, others administer much larger doses. In the work on this thesis Perran describes the favorable effects produced by large doses of hydrochloric acid taken according to the method employed with success by Dr. C. Tournier in his private practice, as also by Dr. Lépine, of Lyons. Dr. Tournier gives hydrochloric acid in the French official dose of from three to four grammes (forty-five minims to one drachm) daily in the following manner: the patient takes fifteen drops of the acid a few minutes after finishing each of the two principal meals, then at the end of half an hour he takes another fifteen drops, and lastly, in certain cases, he again takes fifteen drops after an interval of thirty minutes. This method of taking hydrochloric acid is about the same as that employed by Dr. Ewald, who prescribes fifteen drops of the acid three or four times at quarter-hour intervals. However, the hydrochloric acid of the German pharmacopoeia contains twenty-five per cent. of the gaseous acid, while that of the French pharmacopoeia contains about thirty-five per cent. Tournier therefore employs a larger dose than Ewald. Thus administered the hydrochloric acid would be tolerated and its use prolonged without inconvenience for several months. This medication is indicated in gastric hypochloridia in general, and especially in henteric diarrhoea accompanied by extreme hypoauidity of the contents of the stomach. These patients have very slightly accentuated gastric disorders. One observes neither palpitation nor swelling, neither pain nor flatulence. Gastric movements are preserved and even exaggerated, and the chemical analysis alone shows that the fault lies in a lack of acid in the contents of the stomach. But there is always a henteric diarrhoea occurring generally after each meal, and this disappears in four or five days under the influence of the acid treatment, although it may have resisted all other remedies. A second group of cases, where the use of large doses of hydrochloric acid produces good results, is found in certain gastric conditions with functional hypochloridia, which may be observed in neurasthenic patients, and shows itself especially in alimentary vomitings with no burning sensations and unaccompanied by soreness. The use of hydrochloric acid in these cases does not fail to control these vomitings. Lastly, this drug is especially useful in cases of gastric catarrh with hypochloridia of alcoholic origin, when the troubles consist more especially of alimentary vomitings, distention, sensation of weight after meals, insomnia, and loss of appetite. The conditions which might constitute a formal contraindication to the use of hydrochloric acid are those in which the gastric troubles are accompanied by a pronounced hyperaesthesia of the mucous membrane of the stomach for all acids. It is easy to understand the favorable influence exercised by hydrochloric acid in cases of gastric catarrh in conjunction with hypoauidity; indeed, physiology teaches us that this acid favors the secretion of the gastric juice, the emptying of the stomach, and the disappearance of mucus; further, that it acts as an antiseptic; and lastly, that it is an excitant of the pancreatic secretion. It is, above all, this last property which Tournier invokes in order to explain the curative action of hydrochloric acid in cases of henteric diarrhoea.

The Effect of Aniline upon the Bladder. Prof. Dr. Rehn (*Lancet*, December 17th), at the German Surgical Congress, described some cases of growths of the blad-

der occurring in workmen employed in chemical factories, especially those where fuchsin is made. He expressed his opinion that the vapors developed in the manufacture of fuchsin produced an irritation of the uropoietic system which finally led to the formation of malignant growths. Dr. Leichtenstern, chief physician to the Cologne General Hospital, writing in the *Deutsche medizinische Wochenschrift*, states that long ago he also observed urinary troubles in these workmen, especially in the form of strangury and haematuria. He refers to similar observations made by Dr. Grandhomme, of Hoechst, Dr. Stark, of Cologne, and Dr. Bachfeld. Aniline and toluidine are especially liable to produce irritation of the bladder. The patients in question were employed in the so-called reduction department of the factory, where nitrobenzol is converted into aniline, amidotoluol converted into toluidine, and fuchsin produced from those two compounds. In this department, therefore, the workmen run great risks, and prophylactic measures should be taken. Free ventilation is essential in order that they may not be exposed to the influence of concentrated vapors of the above substances. They should be instructed to give immediate notice to the medical officers whenever any urinary troubles occur, and men suffering from a disease of the uropoietic system ought not to be employed in aniline works. Dr. Leichtenstern in conclusion described two cases of tumors of the bladder lately observed by him in workmen from a well-known Rhinish chemical factory. The first patient was a man, thirty-one years of age, suffering from symptoms of chronic aniline poisoning—yellow-green color of the hair and nails, together with anæmia. He had also for several weeks complained of anorexia and strangury. By rectal palpation a globular and very painful tumor was recognized in the bladder. The bladder itself was so small that only seventy cubic centimetres (two ounces and a half) of fluid could be injected by irrigation. The daily quantity of urine was from five hundred cubic centimetres to seven hundred and fifty cubic centimetres (seventeen fluid ounces to twenty-seven fluid ounces); it was of a dark-green color and contained a small quantity of blood. Casts were never present and the reaction was acid. In course of time other tumors formed in the bladder and could be felt on both sides of the symphysis, while the capacity of the bladder decreased so much that it would hold only forty cubic centimetres (an ounce and a half) of fluid. The treatment consisted of hot poulticing, hot baths, opium suppositories, and subcutaneous injections of morphia, the effect of which was that the patient gradually improved, the capacity of the bladder increased, the urine became normal, and the tumors disappeared. After six weeks the man was able to leave the hospital with only a slight degree of anorexia and strangury. From this rapid recovery it was evident that the growths were not malignant, but that they were due to acute submucous proliferating cystitis. The second patient unfortunately died. He was fifty-one years of age, had been employed for many years in the factory, and went to the hospital with nearly the same symptoms as those in the preceding case, but the tumors were much larger and were perceptible above the symphysis. A cysto-cop was impossible, for the cavity of the bladder was practically obliterated, and the catheter could not make its way to the base of the tumors. Notwithstanding treatment, as above described, the growths increased and a cystostomy was therefore performed. The bladder appeared to be changed into a great mass of growths and was completely removed, the

ureters being brought out into the wound. The patient died two days afterward. The necropsy showed that the tumors were reticular polymorphous sarcomata and had grown through the submucous tissue. The cause of the disease was evidently a chronic irritation of the bladder caused by the vapor of aniline, its pathogenesis being comparable to that of the sarcoma affecting chimney sweeps and workers with paraffin.

A Green Color as Indicative of Gangrene of the Intestine.—Begoïn (*Centralblatt für Chirurgie*, December 2d; *Journal of the American Medical Association*, December 31st) states that he found an eight-day incarcerated loop a "fine green Florentine bronze color" at the herniotomy. The loop was not reduced and the patient died four hours later, when tests of the green portion proved that it was not gangrenous. The portion of the intestine was filled with water at a strong pressure, and only an apparently sound part split. He also states that the intestine can be colored green with bile alone, and that a light-green color does not necessarily imply any alteration in the intestinal wall. A yellow-green, dark, black, or bottle-green are of worse significance, but at the same time they do not necessarily indicate a serious deterioration in the intestinal wall.

The Yukon College of Physicians and Surgeons.—According to the *Canadian Journal of Medicine and Surgery* for January, the establishment of a Yukon College of Physicians and Surgeons, and the election of a council for the same, have taken place. There were some twenty-five Canadian practitioners in Dawson and vicinity, and a number of American physicians who were practising in spite of the Northwest Territories' ordinance. The Canadians found it necessary to incorporate themselves into a legal body for the purpose of protection and mutual help.

At the election held on the 5th of October, 1898, the following gentlemen were elected members of the Council of the College of Physicians and Surgeons of the Yukon Territory: President, E. D. Dunn; vice-president, R. R. Macfarlane; registrar, A. F. Edwards; and J. W. Good and H. H. Hurdman.

The first examination was announced for October 15, 1898, and the following examiners were appointed: Surgery, J. W. Good and E. L. Barratt; medicine, R. R. Macfarlane and E. G. Scott; midwifery and gynaecology, E. P. Thompson and W. G. Hepworth; medical jurisprudence and sanitary science, J. A. Sutherland and W. A. Richardson.

Since the ordinance assented to by the executive council, an amendment has been added which allows all *bona fide* medical practitioners, practising in the Yukon Territory at the date of the establishment of the College of Physicians and Surgeons, who were able to produce certificates of having attended a medical college for three years and a diploma of qualification from the same, to be eligible for admission to the College of Physicians and Surgeons upon passing an examination and paying one hundred dollars to the registrar. This amendment holds good only until the close of the first examination.

As it now stands the regulation with reference to the practice of medicine in the Yukon Territory is, in brief, that (1) licentiates of Quebec, Manitoba, and the Northwest Territories are eligible to practise medicine in the Yukon Territory on the presentation of their licenses and the payment of a fee of one hundred dollars. (2) Those who can present certificates of attendance for four years,

or a diploma of qualification from a recognized school of medicine, are eligible to practise in the Yukon Territory upon passing the examination of the medical council of the territory and the payment of one hundred dollars to the registrar.

Deaths of Eminent British Physicians.—We learn from the *British Medical Journal* for December 24th that Dr. A. A. Kanthack, professor of pathology in the University of Cambridge, England, died on December 21st. The deaths are also announced in the same journal of Dr. Munn, Harveian Librarian of the Royal College of Physicians of London, and the compiler of the *Roll of the Royal College of Physicians of London*, a work of great historical and antiquarian value as well as of Dr. Charles John Hare, consulting physician to University College Hospital, London.

Plague in Madagascar.—According to the *Journal des sciences médicales de Lille* for December 17th, a dispatch from Tamatave announces the outbreak of a disease seemingly identical with the bubonic plague of the Orient. The origin of the epidemic can not be ascertained, but examination of the buboes has revealed the presence of the bacillus of Yersin.

The Acquittal of the Christian Scientists in the Frederic Case.—The *British Medical Journal* for December 24th says:

"So far as the law courts are concerned, the last word has been said as to the circumstances attending the last illness and death of Mr. Harold Frederic; and very unsatisfactory (to the public) that last word is. The coroner's jury, it will be remembered, returned a verdict of manslaughter against the two ladies, Miss Kate Lyon, who lived with him at Kenley, and appears to have had charge of his establishment there and to have assumed the general charge and control of the patient throughout his last illness, and Mrs. Mills, the Christian Scientist "healer," who was called in by Miss Lyon. The treasury took up the case, and after a full inquiry extending over several days before the Croydon justices withdrew the charge against Miss Lyon, having come to the conclusion that no jury would convict her, but asked for a committal against Mrs. Mills. The magistrates, however, were of opinion that the evidence against Mrs. Mills was not sufficient to justify them in sending her for trial, and they therefore discharged her also, stating that they came to this decision with the less difficulty because the defendants would necessarily be indicted on the coroner's inquisition, upon which the treasury could obtain the decision of the higher court, so that justice could in no sense be defeated by the refusal of the magistrates to commit for trial. When, however, the case came before the Central Criminal Court in due course last week, counsel for the crown announced that, after consulting with the attorney-general, he did not propose to offer any evidence against either of the defendants. Mr. Justice Hawkins, the presiding judge, directed the jury that under these circumstances they had no alternative but to return a verdict of not guilty, as no evidence was before them on which any other verdict was possible. But the learned judge pointed out that he was not responsible for the withdrawal of the charge, and emphatically declined even to share the responsibility in any degree with the crown. From some cause not explained it seems that no copy of the depositions taken before the coroner or magistrates had been sent to the judge. The judge said he would have

read the depositions if they had been sent to him, and might then have assented to the course proposed by the crown or might not have assented. Those who know Mr. Justice Hawkins will feel pretty confident that in a case of such great public interest he would have stated his reasons for assenting or dissenting, and in doing so would have thrown some much-needed light upon the law and its relation to the facts of this case.

"As we said in a previous notice of this case, 'the point on which an authoritative deliverance is required is how far it is lawful for those about a sick person, presumed to be incapable of forming an intelligent judgment for himself, to neglect ordinary medical treatment, and rely solely on "faith healing." As no statute deals with the case of adults in general over sixteen years of age, the question can only be answered by reference to the principles of the common law, and these principles do not appear to recognize any positive legal duty on the part of any person to supply medical aid or medicines to a sick adult unless that person has in fact the charge and control of the patient for the time being, and the patient is in fact incapable of taking care of himself. In such circumstances the common law holds the person responsible for procuring whatever is necessary for the patient—food, clothing, fire, etc.—and it would be a question for the jury to say whether, in the particular circumstances of the case before them, medical aid and medicines could reasonably be considered necessities. If this was answered in the affirmative, there would be the further question, Why were they not supplied?"

"On this point Mr. Justice Wills, in his charge to the jury in the case of Senior, which we noticed last week, directed the jury that 'in order to make out a case of manslaughter by negligence of this kind, purely at common law, the negligence must be gross and wanton; so much so as to indicate something, at all events, of an evil mind, and that it was impossible to say that of the prisoner, who was shown to have spared neither expense nor care, and to have taken in all respects but one (namely, the procuring of medical aid and medicines) every precaution to do the best for the child.'"

"For his failure to provide medical aid and medicines Senior was sentenced to four months' imprisonment with hard labor. But it is clear that under the common law Senior could not have been convicted of criminal neglect, and the statute under which he was convicted is expressly limited to patients under sixteen years of age. But had there been a similar provision applicable to adults the case against Miss Lyon would have been narrowed down to the question, Was Mr. Harold Frederic capable of taking care of himself? Whether such a provision would be desirable in the interests of the public, and whether if desirable the legislature could ever be persuaded to enact it, are delicate questions which we can not discuss at present."

The American Medico-Surgical Bulletin. We learn from the December issue of this journal that it has been acquired by Messrs. Merck & Co., of New York, who will discontinue its publication with that number, and will publish in its place Merck's *Archives of the Materia Medica and its Uses*.

Christian Science vs. Law.—The *New York Times* for January 6th contains the following admirable remarks by Dr. Frank S. Billings:

"It seems the Court of Common Pleas in Ohio de-

cides that the Christian Science healer has not the responsibility in regard to the treatment of the sick that the law imposes on all other practitioners of medicine, regular and irregular. The learned judge of this court in Cincinnati holds that the rites she (the Christian Science healer) performed were religious and not medical, and therefore not within the State medical law, under which she was prosecuted. It is unfortunate that one can not tell whether the legal objections were simply a technical evasion of the law so disgracefully common in this country, or that the law did not cover the case in point. From the general character of the case in question and the remarks of the judge there seems no doubt that the Christian Scientist would have been guilty of malpractice leading to death—in plain English, professional murder—had she been either an ordinary charlatan or a regular medical practitioner. She escaped because 'the court holds that the rites (practice) she performed were religious and not medical.' This decision is based on the law guaranteeing the free right to religious opinions, but the learned judge seems to be entirely unaware that that law has reference to opinions, to theories, as to the existence of God alone, and in reality has no reference to rites or actions, which is an entirely different question. Under our laws a Hindu could come to this country and freely utter the principles of his religion and perform many of its rites, but would our law protecting 'freedom of religion' permit the widow of such a Hindu to ascend the funeral pyre of her husband and sacrifice herself through one of the holiest rites and moral obligations of her religion? Suppose the Christian Scientists, or some other new sect, should claim to be 'Abrahamites' and that child sacrifice was their holiest rite (it is quite possible; nothing in this line seems too absurd to flourish in this country of free and glorious license to ignorance), and put it in practice, would that not be a religious rite according to the learned judge of Cincinnati? Such absurdities as that are exactly similar to the rites of the Christian Scientists. They come under criminal, and not civil, law. Here is one of the richest of several cases that have come to my knowledge: Mrs. — was the pretty young wife of a clerk. Her mother was a maniacal Christian Scientist. When it came time for Mrs. — to be confined the husband was told he might go to his business, and the mother (mother-in-law) took the case in hand, aided by a Christian Scientist healer. The poor girl began to suffer, and the fool woman put a Bible on her abdomen and told her that her pains were all resignation, that the Lord never gave people pain, and so on, *ad nauseam*. The agonies of that poor child must have been terrible, for neighbors heard her screaming and begging for a physician, but these Christians would never let her. Finally the pain stopped; no further screaming was heard. The reason was that the child had ruptured the womb and was in the abdominal cavity of the mother. Then there was rushing in mad haste. The husband was sent for; the physician was sent for; but too late; the woman died of hemorrhage and the child died of death. 'Two murders.' But were these women murderers? Not a bit of it. Public sentiment was against them, of course, and no official dared to run a law suit. It was God's will to take his dear one, that was it, and the scientist and a Christian Scientist are the *culprits*."

Plague in England.—According to the *British Medical Journal* for December 11th, the *Red Cross Society of Bombay*, on its arrival from Calcutta at Plymouth,

England, on December 24th, had on board a patient suffering from plague. He was landed and isolated.

The Medical Department of Kentucky University.—The annual session began on January 2d. On December 31st the following-named gentlemen, formerly professors in the Kentucky School of Medicine, were elected full professors in Kentucky University of their respective departments: Dr. J. B. Marvin, professor of the principles and practice of medicine and clinical medicine; Dr. J. M. Holloway, professor of surgery and clinical surgery; Dr. C. W. Kelly, professor of anatomy; and Dr. S. E. Woody, professor of chemistry and diseases of children. On January 1st the university celebrated the one hundredth anniversary of its foundation. It was originally Transylvania University.

A Proposed Provincial Bacteriological Laboratory for New Brunswick.—The *Maritime Medical News* for December states that a movement is on foot to bring about the establishment of a provincial bacteriological laboratory, under the care of a competent bacteriologist, for the province of New Brunswick. The provincial board of health has had the matter under consideration for some time, and has urged the local government to make provision for the salary of the bacteriologist in charge. It is proposed that every physician in the province shall command, *without charge*, the services of the bacteriologist for the early diagnosis of diphtheria and typhoid fever. Should the laboratory be established, it is expected that a small fee will be charged for sputum examinations and for tumor cuttings.

The *News* expresses the hope that the entire profession in New Brunswick will unite in support of the provincial board of health in its effort to secure the establishment of such an important and necessary adjunct to the practice of medicine, and such a valuable means of preserving the public health.

The Charcot Statue.—On December 4th, according to *Lyon médical* for December 18th, the statue of the late Professor Charcot was inaugurated at the Salpêtrière. Remarks were made by M. Brouardel (the president of the committee), the president of the Paris municipal council, Professor Raymond, Professor Cornil, and the minister of public instruction.

The Society of Medical Jurisprudence.—The special order for the last regular meeting, on Monday evening, January 9th, was a paper by the president, S. B. Livingston, Esq., on Citizenship and the Age of Maturity. The society's annual dinner will take place at the Waldorf-Astoria on February 18th.

Lectures on Teratology and Antenatal Pathology in the University of Edinburgh.—On the recommendation of the medical faculty and senatus of the University of Edinburgh, and with the permission of the university court, Dr. J. W. Ballantyne, lecturer on midwifery and gynecology in the Medical College for Women, Minto House, will deliver a series of six lectures on teratology and antenatal pathology within the university (new medical buildings). The lectures, which are free to the members of the medical profession, will be given in the medical jurisprudence class room, at 5 o'clock p. m., on consecutive Fridays in February and March, 1899. The following is a syllabus of the lectures: Lecture I, February 3d: The scope, interest, and importance of antenatal pathology, including teratology, and its relation to

neonatal and postnatal pathology and to the other branches of biological and medical science. Lecture II, February 10th: The pathology of the fetus; fetal diseases as influenced by the intra-uterine environment, the placental factor, and the embryonic factor; diagnosis. Lecture III, February 17th: The pathology of the embryo; teratology; embryonic malformations and monstrosities as influenced by embryonic physiology, the amniotic factor, and the germinal, or pre-embryonic, factor; classification and diagnosis. Lecture IV, February 24th: Teratogenesis, or the causes of monstrosities and malformations; the ultimate causes and the mode of action of the causes of teratological phenomena; experimental teratology. Lecture V, March 3d: The pathology of the germ; diploteratology; the intraconceptional factor in teratology; the preconceptional factor, or the heredity of diseases and deformities. Lecture VI, March 10th: Antenatal therapeutics; possibilities and probabilities; the problems to be solved; fetal, embryonic, and germinal therapeutics.

The Hospital for Scarlet Fever and Diphtheria.—The board of governors consists of Dr. John Winters Brannan (president), Dr. T. Mitchell Prudden (vice-president), Mr. George F. Crane (treasurer), Mr. Paul Tuckerman (secretary), Mr. James J. Higginson, Mrs. John W. Minturn, Dr. Alvah H. Doty, Dr. Hermann M. Biggs, and the president and the commissioner of the city board of health (*ex officio*). The consulting physicians are Dr. E. G. Janeway, Dr. A. Jacobi, Dr. W. H. Draper, Dr. R. H. Derby, Dr. F. P. Kinnicutt, Dr. A. A. Smith, Dr. J. W. Brannan, Dr. Gorham Bacon (otologist), and Dr. H. Holbrook Curtis (laryngologist). The visiting physicians are Dr. W. H. Katzenbach, Dr. Floyd M. Crandall, Dr. W. K. Draper, Dr. R. J. Carlisle, Dr. Egbert Le Fevre, and Dr. Thomas S. Southworth. The hospital is situated at the foot of East Sixteenth Street, facing the East River. It is intended for pay patients. There are two separate pavilions, entirely independent of each other, one for scarlet fever and one for diphtheria. Each pavilion is equipped with its own physician, staff of nurses, servants, etc. There are no wards. Each patient has his own private room. The hospital is a private corporation, controlled by its own board of governors, and is not connected with any other institution. The charges for rooms, including nursing and the services of the resident physician, are thirty dollars a week, payable weekly in advance. If the services of the visiting physicians are required, their charges will be in addition. Patients may be attended by their own physicians, if it is so desired. Children may be accompanied by their mothers. Patients intended for the hospital must not be removed from their apartments until the resident physician has been notified (telephone call, 2880 Eighteenth Street) and the requirements of the board of health have been complied with. The hospital has its own ambulance and coupé service.

The Death of Professor Laboulbène is announced in the *Journal des praticiens* for December 24th as having recently taken place.

The Tenth Congress of Alienists and Neurologists.—According to the *Nouveau Montpellier médical* for December 18th, the tenth Congress of Alienists and Neurologists will take place at Marseilles on April 4th of this year under the presidency of Dr. Dauteronde, chief physician and director of the Asile de Blois.

Original Communications.

FURTHER OBSERVATIONS ON COXA VARA,
WITH PARTICULAR REFERENCE
TO ITS ETIOLOGY AND TREATMENT.*

By ROYAL WHITMAN, M. D.

SINCE the publication of my former paper on this subject, four years ago,[†] the meagre literature has been considerably enlarged, and the somewhat cumbersome term, bending of the neck of the femur, has been displaced, at the suggestion of Hofmeister, by the shorter if less definite one of coxa vara.[‡]

During this time twenty-two additional cases have come under my observation, some of which present peculiarities worthy of attention in their bearing on the etiology and the treatment of the affection.

Coxa vara is, in brief, a depression of the neck of the femur, in most instances following the line of the least resistance, downward and backward, but occasionally directly downward, or even downward and forward. It is one of the group of deformities of the lower extremity due to inherent or acquired weakness of structure or to disproportionate strain, or both, in which knock-knee, bowleg, and the weak foot may be included. The effect of the deformity may be explained by the change in the anatomical relation of the parts involved, and its symptoms are such as might be expected as a result of the progressive transformation of the internal structure of the weakened part, and of the sympathetic and accommodative changes in the joint and in the surrounding muscles.

Coxa vara is of particular interest and importance because it has been, until very recently, entirely overlooked, and because it has been and still is very generally mistaken for tuberculous disease of the hip joint. Indeed it is, apparently, to such a mistake that we owe the identification of the affection.

Bowleg and knock-knee are self-evident, but this deformity of the hip is concealed from view, and in the early stage it is somewhat difficult to diagnose, unless one is familiar with its characteristics, and is experienced in the details of physical examination.

Other deformities of this class are not only self-evident, but they commonly appear and are treated in early childhood, when the cause of the weakness of the bones, general rachitis, is apparent also. Coxa vara is not often an affection of this period of life, or, if

least, the symptoms are latent until later childhood or adolescence, when it usually develops as an isolated deformity of one or both hips, in many instances in patients who present no other evidence of weakness or disease. Finally, in the simple distortions of the legs, the deformity is of greater importance than the discomfort or disability that it causes; but in coxa vara the depression of the neck of the femur entails a partial displacement or disarrangement of the components of the joint that may cause disability out of proportion to the apparent deformity.

The characteristic symptoms and the effects of coxa vara are explained by the deformity, and the diagnosis can be made only by the physical examination. Thus it seems proper to describe the peculiarities of the affection before considering its pathology or possible causes. In the normal subject the neck of the femur projects upward, inward, and slightly forward, forming an angle with the shaft of from one hundred and twenty-five to one hundred and thirty degrees. This allows for the abduction of the thigh and for the proper leverage of the muscles attached about the greater trochanter. If, then, the neck becomes depressed to a notable degree—for example, to a right angle—the range of abduction will be restricted, because the neck of the bone will come into contact with the upper border of the acetabulum. If the neck is, at the same time, forced backward, the shaft will be rotated outward and the range of inversion of the limb will be diminished. The effect of the deformity in restricting the other movements of the joint is less direct. Extension remains unaffected, or its range may be increased even; flexion is limited by the abnormal tension on the capsule, because extreme flexion would throw the displaced head out of the acetabulum. For the same reason flexion increases the inward and outward rotation of the limb.

If, on the other hand, the neck is displaced forward, extension and eversion may be limited, while flexion and inversion are unrestricted. The deformity, in the restriction of motion are misused, primarily, to the distortion of the bone and by tension on the capsule, but their effects are exaggerated by the accommodative shortening of the muscles and, in some instances, by active spasm and contraction. Thus, the active shortening of the limb, corresponding to the depression of the trochanter, may be but half an inch, but the distance more than an inch over the elevated trochanter. In the latter instance the a quo ante position of the limb, the abduction of the limb and the rotation of the limb, the tilting of the pelvis, and the position of the trunk, the equality of the limbs, and the position of the feet, are depressed. The head of the femur is displaced, the locomotion is extremely painful, and the patient is disabled. It is caused, in proportion to the degree of the contraction of the adductors, by a weakness of the muscles of the progress of the deformity. It is caused, in proportion to the degree of the contraction of the adductors, by a weakness of the muscles of the progress of the deformity.

In fact, unilateral coxa vara, during the progressive stage, corresponds, in its symptoms and physical signs, so closely to fracture of the neck of the femur during

FIG. 1.—Photograph of Case 1, June, 1893.

the stage of repair that but for the history it could not, in many instances, be distinguished from it in patients of the same age, either by examination or by the X-ray photograph.*

A secondary effect of the deformity is disturbance of the equilibrium, and thus a change in the contour of the body. If, for example, the necks of both femora are depressed backward, the support of the body is displaced forward, and the normal lordosis is diminished. If, on the other hand, the inclination of the necks is downward and forward, the trochanters are displaced backward and upward; thus the lordosis is increased and the range of outward rotation of the limbs is restricted.

From the nature of the deformity one may readily explain the symptoms. In unilateral coxa vara the slight limp due to the shortening of the leg, a certain stiffness about the joint after a period of inactivity, and dull pain or discomfort, usually referred to the front of

the thigh, are the most prominent symptoms. These are, in most instances, supposed to be due to rheumatism, or are thought to be "growing pains," until the deformity is more advanced, when a diagnosis of hip disease is usually made. In young children there may be no complaint whatever. On the other hand, in the adolescent, there are usually sensations of weakness and awkwardness and at times, after overexertion or long standing, severe pain about the joint may be experienced. These symptoms are accounted for by the sympathetic disturbances in the joint, as well as by the partial displacement and strain upon the ligaments, in which particular the deformity resembles more nearly the weak foot than simple bowleg or knock-knee.

If the deformity is bilateral, the limp is replaced by a peculiar swaying of the body from side to side, due to the restriction of abduction, a gait resembling that characteristic of knock-knee, in which the legs are alternately lifted by one another. The awkwardness and

FIG. 2.—Photograph of Case 1, September, 1893. Shows, when contrasted with Fig. 1, the relative prominence and elevation of the trochanters, also the absence of the normal lumbar lordosis.

weakness are more marked, and in extreme deformity, in which the legs are crossed, locomotion may be impossible.

* *Colo. Fracture of the Neck of the Femur in Childhood.* *Transactions of the American Orthopedic Association*, vol. 5.

In some instances, particularly in the bilateral form, coxa vara may be accompanied by other evidences of weakness in the lower extremity, more particularly by flat-foot, to which the eversion of the leg predisposes; but in the majority of cases there is, as a rule, little evidence of weakness, and none whatever of general rickets.

The important points in the physical examination are, then, the elevated, prominent, and displaced trochanter, as may be demonstrated by Nélaton's line and Bryant's triangle, and the actual shortening of the leg and the peculiar and unequal limitation of the range of motion dependent upon the deformity. In progressive cases, forced passive motion causes discomfort, and at times it may be resisted by voluntary and involuntary contraction of the muscles. This is, however, rather unusual. There is commonly a certain amount of muscular atrophy, more marked in the thigh than in the leg, which corresponds to the duration and to the degree of the disability.

Differential Diagnosis.—There are very few affections for which coxa vara may be mistaken. One of these is congenital dislocation of the hip, in which the limp, the elevation and prominence of the trochanter, and particularly the abnormal lordosis and waddle of bilateral misplacement are similar to that exceptional form of coxa vara in which the necks are turned forward. But the very fact that a dislocation is congenital, that its symptoms are noted from the moment that the child begins to walk, should exclude coxa vara, which is, as a rule, a deformity of late childhood or adolescence.

In exceptional cases, the depression of the neck of the femur is sufficient to cause symptoms at an early period of life as one of the deformities of general rha-

ple physical examination are these: In congenital dislocation, if the thigh is adducted and flexed to its extreme limit, the neck and head of the displaced bone may

FIG. 4.—Photograph of Case I, September, 1886. Shows the prominence of trochanters.

FIG. 3.—Third photograph of case I.

chitis, and it is possible that coxa vara might be congenital. In such instances the diagnosis may be more difficult. The important diagnostic points in the sim-

be felt above and beyond the trochanter, and there is in addition an abnormal laxity of the joint that allows the trochanter to be moved up and down on the pelvis; in coxa vara there is no abnormal mobility. The trochanter becomes more prominent on flexing and adducting the limb, but neither the neck nor the head of the bone can be made out.

From actual disease of the head or neck of the bone the diagnosis is, as a rule, easily made. In disease, depression of the bone is a late symptom, always preceded by more severe symptoms than those of coxa vara, and always accompanied by muscular spasm, by limitation of motion in all directions, and by prominent distortion of the limb. If tuberculous disease were sufficiently advanced to cause weakness and distortion of the neck, the evidence of its presence in the tenderness, swelling, or abscess would be conspicuous. This case is loaded with more force of more acute disease of which the most common form is infective osteomyelitis. In coxa

vara, on the other hand, the elevation and prominence of the trochanter, denoting the characteristic deformity, are entirely out of proportion to the local discomfort. Motion is usually but slightly limited, never equally in

FIG. 5.—Photograph of Case I, May, 1894. Shows the apparent shortening of the leg—relative to the length of body, as contrasted with Fig. 1.

all directions; thus extension may be abnormally free, while permanent adduction of the limb, due to the deformity, may be present. There is practically never local tenderness, and, of course, no suppuration or other evidence of destructive disease of the bone. In rare instances, after injury or overexertion, pain on motion and spasm of the muscles, resembling the symptoms of a strain or sprain or rheumatism, may be present, but these disappear quickly on rest, leaving only the evident deformity of the neck of the bone, on which the symptoms depend.

Fracture of the neck of the femur is not an uncommon accident in childhood, and, as has been stated, it results in a deformity that is practically traumatic coxa vara. The history of the accident should explain the cause of the symptoms.

Ætiology of the Deformity.—As is well known, there are two periods of life when static deformities of the

bones of the lower extremity appear, or, at least, increase to the point of attracting attention. One is in early childhood, when deformity is most often the direct result of evident general weakness due to rachitis; the other is in adolescence, which is popularly recognized as a period of weakness, when the stability of the tissues is lessened by rapid growth and when the strain of laborious occupation is often added to the increase of body weight.

Coxa vara more often appears at this latter time, when there is no evidence of general weakness or disease that would account for the local deformity. For this reason, doubtless, coxa vara as an affection of adolescence was not recognized until 1889, when E. Müller* obtained a specimen by resection, and, by comparing the symptoms with those of similar cases under observation, was enabled to describe the peculiarities of a “new deformity.” It should be stated, however, that depression of the neck of the femur, as one of the deformities of childhood, had been recognized by Fiorani in 1881. He described in detail fifteen cases that had been mistaken by others for congenital dislocation of the hip, and suggested treatment, dietetic, instrumental, and operative. The article appears, however, to have attracted little attention, and, as has been stated, the deformity is of much greater importance when it appears in later life than as an ordinary rachitic deformity.†

From my own experience it would seem that one rarely has the opportunity to make a diagnosis of coxa vara as a part of the general rachitic deformities of early childhood. In fact, I have been able to identify but one case; in this instance the symptoms were not only typical, but the diagnosis was confirmed by an X-ray photograph. (See Fig. 10.) Slight elevation of the trochanter is often found, as was pointed out by Nélaton‡ long ago, but it is usually caused in part by the abducted thighs that accompany general bowing of the legs, and in part by an outward bend of the upper third of the femora.

The comparative infrequency of the deformity is undoubtedly explained by the fact that the neck is very short, and, being inclined less than in older subjects, is thus protected from strain. I am disposed, however, to believe that what may be called a latent deformity acquired at this time may be a factor of considerable importance in the causation of coxa vara of adolescence. As is well known, the angle formed by the shaft and the neck of the bone is considerably less in the adult femur than in that of the child. According to Humphrey, this is the result of a gradual depression coincident with the growth, and comes to an end with it. As it is evident that the strain upon the neck of the femur is increased with its inclination, one may understand how,

* *Beitrag zur Klin. Chir.*, Bd. iv, S. 137.

† *Supra una forma speciale di zoppicamento.* *Gaz. degli ospitale*, 16 and 17, 1881.

‡ *Path. chir.*, t. ii, p. 521.

if the angle be lessened at an early age, the depression might, under favoring conditions, be exaggerated to deformity at a later period of life.

My attention was first called to this mechanical factor in the aetiology by an investigation of the later results of fracture of the neck of the femur in childhood.* The primary effect of the injury is a depression of the neck of the bone, often to a right angle with the shaft, as in older subjects. As I have already reported to this association, an investigation of these cases several years later showed a marked increase of the deformity, due to a further depression of the neck. Two of the cases in which, when discharged from treatment, there was practically no disability or deformity, when again examined presented all the characteristics of extreme coxa vara. In these cases it was evident that the deformity had increased simply because the depressed bone, subjected to greater strain because of its abnormal position, had given way.

In many cases of adolescent coxa vara, careful questioning will elicit a history either of weakness or of rhachitis in childhood, and of the latter affection evidences may still remain. In such instances the inference seems reasonable that the neck of the femur may have been slightly depressed and thus exposed to overstrain at a later stage of development. Or, again, slight or pronounced depression may be a congenital peculiarity, or the neck of the bone may be simply structurally weak and thus unable to withstand the strain that may be put upon it. When one considers that the angle of inclination of the neck,† as observed in adult femora, may vary between one hundred and ten and one hundred and forty degrees; that it may project either forward to an angle of twenty degrees, or backward to one of twenty-five degrees with the shaft, and the other differences in the form, size, and shape that may be observed in the femora of apparently normal subjects, there seems more likelihood that an inherited or acquired weakness, either of position or structure, may be the important predisposing cause of the deformity. The exciting causes would then include the instability of rapid growth, overstrain, overweight, and injury.

The alternative hypothesis must be general or local disease. General active rhachitis is practically never present in the ordinary type of case, and osteomalacia and osteitis deformans need not be considered, because depression of the neck of the femur is, in such instances, merely an incident in the general distortion of the skeleton. Some of the German writers have suggested a new disease of the bone to account for the weakness—so-called local rickets or local osteomalacia—but the examination of the few specimens that have been obtained offers little support to such a theory. In one, from an adult subject, the structure was normal; others, exam-

ined during the progressive stage, showed congestion or softening and slight irregularity of the epiphyseal cartilage. But these are changes that one would expect to find in a bone that was bending or breaking under over-

FIG. 6.—Photograph of Case I, May, 1898, five years after the first examination, showing the effect of the operation on the right femur, also the improvement in the general condition.

strain. Improper surroundings, insufficient nourishment, or debility from any cause, undoubtedly lessen the resistance of the bones as of other parts, but the presence of actual local disease is by no means necessary to explain the deformity of the usual type, at least.

As has been stated, the physical effects of the deformity are explained by the nature of the deformity itself, but the symptoms vary according to its duration, to its progress, and with the age and susceptibility of the individual. The depression of the neck increases until the resistance of the compressed bone prevents further deformity, and in many instances stability is not assured until the head of the femur rests upon the shaft in the neighborhood of the trochanter major. If the deformity does not develop until adolescence, its progress is usually comparatively rapid, but if the affection begins in early childhood, its progress may be more gradual and the deformity is likely to be greater. From the symptoms in these cases it would appear that the depression may be intermittent in its progress, as shown by intervals of discomfort in long periods of important health,

* Transactions of the American Orthopaedic Association, vol. x.

† Humphreys. *Journal of Anatomy and Physiology*, vol. xxvi, 1890, p. 236.

although, as a rule, the child is considered to be somewhat weak and awkward at all times.

When stability is finally assured, the symptoms of discomfort disappear and the gradual accommodative

FIG. 7.—Case II. Shows the tilting of the pelvis and the apparent shortening of the leg in unilateral coxa vara. See skingram (Fig. 8).

changes in the structures about the joint lessen the effect of the deformity.

In the unilateral form the limp alone remains, and even in double coxa vara of an advanced degree the patient walks about with a shuffling gait with surprising ease.

Treatment.—The treatment of coxa vara may be preventive or operative. If the diagnosis is made in the early stage, one may hope, by removing the strain of occupation or overexertion, or, in the unilateral deformity, by the use of a perineal crutch-splint, to check its progress. Together with the support, massage, exercise, and passive forcible manipulation of the leg in the direction of limited motion should be employed. In all cases supervision will be required to prevent overstrain of the weakened part during childhood and adolescence, or until the period of growth has been completed.

Operative treatment may also be preventive; for example, one may attempt to replace the depressed neck in its normal position by the removal of a cuneiform section from the base of the trochanter. This operation I have performed in three instances for the relief

of coxa vara. Two of them were cases of the traumatic form (fracture of the neck of the femur). The operation was successful in every case, and the first has been under observation for more than a year. It would seem to be indicated in deformity of early childhood in which the depression is likely to be slowly progressive, and finally extreme.

The other operation is intended, primarily, to relieve the effects of the deformity, of which the most disastrous is fixed adduction of the leg. In two cases of this character linear osteotomy below the trochanter minor permitted me to abduct and rotate the shaft inward to its normal position with complete and permanent relief of the disability. This operation should be performed whenever the depression of the bone prevents the abduction necessary for the proper use of the limb. Even if the affection is in the progressive stage, the fixation during the stage of repair and the nutritive changes consequent upon it seem to exert a favorable influence upon the structures within the joint.*

After union of the divided parts is firm, a perineal crutch should be employed for several months, together with exercise and massage, as already mentioned.

The following cases are described in order to illustrate the different types of the deformity:

CASE I. *A Case of Bilateral Coxa Vara in an Adolescent, illustrating the Course of the Affection, its Symptoms, and its Treatment by Operation; observed from its Inception to its Final Cure; with Photographs, showing*

in June, 1893. Except for a somewhat exaggerated eversion of the feet, there was nothing peculiar in his appearance. In infancy he was said to have had weak ankles, and the flat feet were of indefinite duration, but had never caused discomfort. For two years he had been working hard as a grocer's boy, and at one time, about a year before his first visit to the hospital, he had noticed a peculiar soreness and stiffness about the right hip that were thought to be "growing pain," symptoms that were relieved by a long vacation. On his return the usual work was resumed, and soon after the discomfort again became apparent and more troublesome; recently similar symptoms had appeared on the other side. These symptoms were, as he expressed it, a feeling of fatigue and pain referred to the joint and to the front of the thigh, and a stiffness and discomfort about the hip after sitting or remaining long in one position. These symptoms were increased by overwork and relieved somewhat by rest.

On examination, the eversion and flatness of the feet were very apparent; there were slight knock-knee and slight hyperextension of the knees on both sides; the gait was somewhat rolling in character; the trochanters were slightly elevated above Nélaton's line, more prominent than normal, and displaced forward. The lumbar lordosis was diminished. Motion at the hip joints was painless; it was unrestricted in flexion and extension; abduction was limited to about one third of its normal range, and inward rotation was checked when the feet became parallel with one another. There was slight atrophy of the thighs, and the circulation in the lower extremities seemed to be impaired. The patient was advised to discontinue his work and to employ massage and exercises, but this advice was disregarded. Three months later he again appeared at the hospital, at this time able to walk only with much effort, the body swaying from side to side in a marked and peculiar manner. The peculiarities that have been described had become greatly exaggerated. Behind each prominent trochanter there was a deep sulcus; the normal lumbar lordosis was absent. Abduction of the legs was very greatly restricted, and flexion was only possible when they were crossed—that is, flexion caused adduction of the thighs and greatly increased the outward rotation. Four months later the patient could walk only with crutches, the right leg being crossed over its fellow. The outward rotation had increased so that the foot rested on its outer border when the patient was lying on the table. With the limbs extended, the greatest possible separation of the knees was three inches and a half; the trochanters were at least an inch and a half above Nélaton's line. In October, 1894, the patient decided to submit to the operation that had been proposed several months before, an osteotomy of both femora, in order to restore the lost abduction.

At the time of operation, when muscular contraction had been relaxed by the anæsthetic, it was found that a few degrees of the range of abduction remained on the left side, and it was decided to postpone the osteotomy of the left femur until its effect upon the other had been ascertained. The right femur was divided below the trochanter minor; the leg was then drawn outward to the limit of normal abduction and the lower fragment was at the same time rotated inward until the foot was brought to the perpendicular. In this attitude a number of Paris spica bandage was applied. The operation was completely successful in restoring the function of the joint. Crutches were used for several months, after

which the patient was allowed to go about. His cure appears absolute, and for the last year he has been working regularly. There has been no increase of deformity on the left side, and, as motion has been restored in the right hip, he experiences no disability from the loss of the range of abduction on the left side.

CASE II. Unilateral Coxa Vara treated by Operation.—A well-developed boy, seventeen years of age, came to the hospital in October, 1896, because of a limp and pain referred to the right hip. The symptoms had been noticed thirteen months before, after he had "overran himself," and the discomfort and disability had steadily increased. The examination showed typical

FIG. 2.—Case II. Unilateral coxa vara of the anterior form illustrating the abnormal lordosis, an attitude simulating that of congenital dislocation of the hips.

coxa vara, with adduction of the limb, caused by muscular contraction, that increased an actual shortening of three quarters of an inch to two inches and a half. Subtrochanteric osteotomy was performed in November in the manner already described. A patellar crutch splint was worn for six months. All symptoms are now relieved, and the patient appears to be well.

CASE III. Bilateral Coxa Vara, Anterior Form, Simulating Congenital Dislocation of the Hips, in which

* A flaccid, encephalic child, born at term, was brought to the hospital at the age of three years because of a limp and pain in the right hip. The child was found to have a bilateral coxa vara of the anterior form, with a marked shortening of the limbs, and a marked lordosis of the spine. The right femur was divided below the trochanter minor, and the leg was drawn outward to the limit of normal abduction and the lower fragment was at the same time rotated inward until the foot was brought to the perpendicular. In this attitude a number of Paris spica bandage was applied. The operation was completely successful in restoring the function of the joint. Crutches were used for several months, after

the Symptoms were Continuous with Infantile Rhachitis.—A boy, nine years of age, was brought to the Vanderbilt Clinic in March, 1897. He had suffered from rhachitis in early childhood, had always been weak, and had always waddled slightly in walking. Recently he had complained of pain in the limbs and back. In appearance the case simulated congenital dislocation very closely, in the increased lordosis, the broadening of the pelvis, and the elevated and prominent trochanters, which were an inch and a half above Nélaton's line. As the femoral necks were displaced forward as well as downward, extension and eversion of the legs were restricted, and the greatest possible separation of the knees was eight inches.

In another case, a boy of eleven, the history and physical signs were almost identical, except that the symptoms had not appeared until the age of five years.

CASE IV. Unilateral Coxa Vara in a Child; the Direct Result of Rhachitis; the Diagnosis confirmed by the X Ray.—In November, 1896, a colored child, two years and a half of age, was brought to the hospital because of a limp. There was no complaint of pain or discomfort other than a certain general weakness caused by rhachitis. On examination the cause of the limp was found to be typical coxa vara of the right side. The actual shortening was three quarters of an inch. The

ing, elevation of the trochanter, eversion of the leg, and pain on motion. From the symptoms that had pre-

FIG. 11.—Skigram of Case V.

ceded the sudden disability, a diagnosis of fracture or collapse of a weakened neck was made, and after time had been allowed for consolidation the brace was removed at night and massage and exercise instituted.

At the present time, the brace, attached to the heel of the shoe, is used as a partial support of the weight during the day. The motions of the joint are practically normal except in abduction. The importance of a proper diagnosis, in substituting active motion for prolonged rest, that would otherwise have been enforced, is self-evident. The deformity is shown by the accompanying Röntgen picture.

This case illustrates the effect of slight traumatism on a weakened and deformed structure—*i. e.*, fracture of the neck of the femur secondary to coxa vara. Injury may be the exciting cause of the deformity also, either by weakening the support at the epiphyseal line or actually displacing the epiphysis.

Finally, simple fracture of the neck of the femur is, after union has taken place, typical coxa vara.

Of the twenty-six cases, twenty were in males and six were in females. The deformity was bilateral in five, of the right hip only in fourteen, and of the left in seven.

In three instances distortion of the neck was forward as well as backward; in twenty-four cases the inclination was backward.*

* Since this paper was written four additional cases have come under observation—all of the left side; three in boys, aged respectively four, five, and sixteen years, and one in a girl thirteen years old.

FIG. 10.—Skigram of Case IV.—Coxa vara in a child two and a half years of age, the effect of general rhachitis.

deformity is demonstrated by the accompanying Röntgen picture.

CASE V. Fracture, or Sudden Depression of a Weakened Femoral Neck. A colored girl, thirteen years of age, was brought to the Vanderbilt Clinic in May, 1897, wearing a brace that had been applied for supposed disease of the left hip joint. For about eight months she had been limping and complaining of occasional pain and discomfort about the left hip and thigh, and, according to the mother, the left foot was habitually eversion. Six weeks before the patient's visit to the clinic, descending the street, the leg gave way and she fell backward on the ground. She was carried home and placed in bed, where she remained until the splint was applied. During this time there was no pain except on motion of the leg.

The radiograph showed typical appearance of fracture of the neck of the femur—an inch of actual shorten-

Statistical Table.

NAME.	Date.	Sex.	Side affected.	Age.	Duration.	Direction of the dis- tortion of the backward.	Actual shortening in inches.	Apparent shortening.	History or evidence of former rickets.	Prominent symptoms.

In a total of ninety-six cases, including these and others reported by Hofmeister, Kocher, Leusser, Muller, Ogston, and others, seventy-four were in males and twenty-two were in females. In twenty-three the deformity was bilateral, in seventy-three it was of one side.

The twenty-six patients may be divided into groups, according to the age at which they applied for treatment: Adolescents (twelve to eighteen years of age), 15; later childhood (five to eleven years of age), 7; childhood (less than five years of age), 3; adults, 2.

If, however, the supposed duration of the symptoms be subtracted from the age, the classification according to the time of onset would change the groups as follows: Adolescents, 12; later childhood, 8; childhood, 5; unknown, 1.

The two adults desired examination simply for the explanation of the limp, which had been of many years' duration.

One case was brought for treatment during the course of infantile rickets, and in eight others there was evidence of former rickets in slight distortion of the extremities, or a history of weakness, apparently rickets, in early childhood.

In three instances the symptoms of progressive coxa vara appeared to have been continuous, although remittent, with this early weakness.

A more extended experience has convinced me that coxa vara is much less rare than has been supposed. What has been spoken of as latent deformity is a predisposing cause of deformity of a later period applies equally well to all other static deformities of the class;

and it emphasizes the importance of a more careful oversight of weakly children, for the purpose of detecting and correcting not only the distortions of the bones, but also the improper postures and restriction of motion in the joints that may cause awkwardness or lead to disability.

In addition to the thirty cases of coxa vara, fourteen cases of fracture of the neck of the femur in childhood, traumatic coxa vara, have come under my observation within a few years. Here, then, are forty-four cases of a deformity until very recently unrecognized, the larger number of which were sent to the hospital or clinic for the treatment of hip disease. If such simple disabilities are so mistaken, it may be inferred that other affections of a non-tuberculous nature not infrequently pass as hip disease also.

The first step toward a proper classification of disease of the hip joint on a clinical, pathological, and anatomical basis must be the elimination of affections which are non-tuberculous in their character, and incidentally this paper may be considered as a contribution to this object.

Fowls' Brains in Neurasthenia. The *Lyon medical* for December 18th, quoting the *Revue française de pathologie* for October 31st, says that the Chinese have for a long time treated neurasthenia, headache, and general feebleness by the brain of a fowl. The brain is dried, powdered, and mixed with sugar and aromatic substances and administered in capsules. The *Lyon medical* is a very reliable journal, which can no more be blind our treatment to the value of fowl brains.

HYGIENE VERSUS DRUGS IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

By CHARLES L. MINOR, M. D.,

ASHEVILLE, N. C.

(Concluded from page 55.)

OUR ancestors, feeling after the truth, tried by the use of cold to harden delicate children, their aim being to render them less unduly sensitive to changes of temperature, and while they killed many in their misdirected efforts there was the kernel of a great truth in their attempts. The relaxed, oversensitive skin, unbalanced circulation, and irritable nervous system of the consumptive, is a matter of daily experience to you all. The ease with which he chills, the great activity, but deficient tone of his vasomotor system, the quick flushings and pallors, all show the lack of balance in that great second respiratory system, the skin and cutaneous circulation. The stimulus to the cutaneous nerves of the cold salt water, the deepening of the breathing, the equalizing and toning up of the circulation, the removal of stasis, the increase of metabolism, the stimulation of the appetite, and the general sense of well-being it produces, are all undeniable to those who have tried it fairly. I realize that the idea of a cold bath to a delicate consumptive may seem severe. I have rarely proposed it without at first being met with indignant protest; but begun gradually and cautiously, with variations to suit the individual case, a long and faithful trial of it has convinced me that in all but advanced or actively febrile cases it is a remedy of wonderful power, and you will find few patients who will not learn not simply to tolerate it, but to enjoy it. For its full application in the method I will describe, I select cases with very moderate rise of temperature and no great activity of pulmonary lesion. The patient begins with water at 100° by the thermometer (no guesswork being ever allowed), and its temperature is reduced each morning by one degree, till the final temperature, varying with the case from 70° F. to 55° F., is reached. In this way there will be in the beginning no shock to the system, and the patient becomes easily accustomed to the bath. I regard it as essential that it be taken immediately on rising, the windows having been shut, and a fire lighted an hour beforehand in winter, so that the room shall have reached an equable temperature. No dawdling over other matters is allowed. He rises, strips, and steps warm from his bed into the tub in which are one or two buckets of water at the correct temperature and a handful of sea salt. Saturating his large sponge with water, and standing erect, he holds it over his shoulders and neck and squeeze out the whole volume at once in a shower down his back and chest, thus producing a douche, not to be confused with the slower bath, but very bracing and stimulating. He repeats this rapidly over all parts of his body for about half a minute, jumps out, and rubs

off briskly and actively with a rough Turkish towel, and dresses at once. The result will be a glow all over, and an inexpressibly delightful feeling of invigoration and strength, with a driving away of that languor and weariness with which the consumptive so often rises. If a shock is feared he can moderate it by first wetting his arms and legs from wrist or ankle to trunk, and then proceeding as above. In those whose strength is not great a nurse can do the squeezing of the sponge and the rubbing, but where strong enough the action involved in these motions is valuable in itself.

The only contraindications are lack of reaction, as shown by blueness, gooseflesh, and chilliness, and which, if conditions are proper, will not occur; and in a few cases an aggravation of the cough, which calls for a temporary rise in the temperature of the water.

Not only is the patient delightfully stimulated and braced thereby, but his liability to catching cold and to chilliness is greatly decreased, and his appetite materially benefited. Let me urge on those of you who have not given this method a fair and satisfactory trial to use it, assuring you that carried out in this manner it will not disappoint you. Be careful not to give indefinite directions; as the father of hydrotherapy, Winternitz, says no man can expect results if he orders so potent a remedy with an indefiniteness he would be ashamed of were he dealing with calomel or morphine.

In much weakened cases it is good to begin with cool sponging in bed, followed by frictions, and in this way we can soon prepare them to use the tub.

Exercise, while one of our most valuable aids, is the most generally abused by the public. It is a common experience in Asheville to be called to see patients who, after arrival, having undertaken to treat themselves, and, having experienced the usual tonic effects of such a climate, feel capable of anything, and have undertaken long walks, supposing that they could do nothing so good as to exercise, with a result almost always disastrous; the barely recovering balance in favor of the organism in its fight with sickness is upset, the overtax on the system is too great, fever, exhaustion, or other symptoms return, and I have even seen it the beginning of a fatal dissemination of the disease.

The more exercise that is taken within the limit of their ability the better, but how many know their limit? How few but overestimate it many times! The only safe rule is to exercise short of the point of fatigue, combined with the other of no exercise with a temperature over 100.4°.

Find out your patient's vitality and capacity for exercise. It varies in the widest limits; one apparently strong girl may feel fagged after a hundred yards, another you judge no stronger may easily tolerate two miles without harm. Here, almost more than anywhere else, is where the doctor can be of use to his patient in preventing him from squandering foolishly his small surplus of force. Having found his limit, begin with

that as a maximum, not to be exceeded without orders, which will come as signs of increasing strength permit it. In this way one is able to take a patient who, on arrival, can not walk at all, and by gradual and cautious additions finally enable him to walk his two, four, even ten miles a day with ease. The same thing, if not so easily, can be accomplished in the cities, but, remembering the fatigue of walking on stone pavements, let him take the trolley to the suburban regions, husbanding his strength to use it in those less dusty, more attractive, and purer-aired localities.

After the patient's strength is well on the mend, commence to attack the dyspnoea and to strengthen the heart by the very gradual practice of increasingly steep inclines. In this way we can assist in expanding collapsed portions of the lungs, invigorating the circulation, and improving muscular strength, till finally really steep hills can be taken with ease. In all cases the injudicious zeal of relatives and friends, which prompts them to urge the loved one on to further and further exertions for his supposed benefit, must be guarded against; with a patient improving rapidly—and in phthisis the improvement in subjective symptoms far outstrips that in objective—it is hard for them to realize the wisdom of the Italian motto, *Festina lente*, make haste slowly. Especially when the patient is allowed to drive—an exercise I generally postpone until he can walk a little without trouble—the five, ten, or fifteen minutes allowed at first seems pitifully small and almost a waste of carriage hire. Yet I have lately seen a drive, extended far beyond the limit of my orders, bring back the pyrexia in a case where it had disappeared, and necessitate a recommencing of my work.

Horseback on a easy-gaited, preferably a racking horse, for cases well advanced toward recovery, is an ideal exercise, but where any activity exists it is contraindicated, as any one who has had lung trouble, and who knows from experience how riding a hard-trotting horse makes his weak lung ache and pain, will agree.

Massage, or other passive exercise, I find of great value to prepare cases for beginning to walk, when from long sickness their limbs have wasted from disuse; but the average *masseuse* is apt to be unduly vigorous, and to wish to push the remedy too far and too rapidly. At best, it is but a temporary substitute for walking, and no indoor, passive exercise can ever take the place of an active outdoor one.

In cases where signs of activity in the process have nearly ceased, where râles are disappearing and fever subsiding, and where it is desired, as it is in every case, to increase the capacity of the thorax, and therefore of the lungs, to deepen the chest, to open out the shoulders, I have great confidence in wisely directed pulmonary gymnastics, taken when possible in the open air. The parallel and horizontal bars in a few of the strongest cases can do wonders in expanding contracted chests and increasing vital capacity, whose increase, as shown

by the spirometer, I hold to be an invaluable prognostic sign; but, ordinarily, much milder pulmonary gymnastics are first demanded, beginning with quiet deep breathings while lying with shoulders thrown back, in bed, and advancing them to deep breathings while erect with the mouth closed, with the aid of the gradual raising of the arms from the sides during inspiration till they meet over the head, where breath is held, to fall gradually again during expiration. When this can be done say twelve times with ease, and the deepness of the breathing is sensibly increased, I use the corner chest-exercise, where the patient, standing in a corner, with feet well out, and hands on the converging walls, falls inward with inspiration and forces himself backward with expiration. As a final, and to me unapproachable chest exercise, as valuable and less violent than the horizontal bars, I place that form of Indian-club exercise called the double figure of eight: both clubs, those weighing a pound are sufficient, coming down and inward across the body during expiration, thus making it unusually complete, then crossing and rising across the face to make behind the shoulder during inspiration, which it wonderfully deepens, a small circle, from which point the arms are thrown outward laterally, and begin their downward course again. In certain cases where the respiratory murmur is very feeble, those lazy breathers referred to by Dr. McLean, the pneumatic cabinet I have found invaluable, but its weight and great expense render its general adoption unlikely. By such exercises as these we can, even in the army of superficial breathers, whose members so largely form the recruits for the still larger army of consumptives, soon get marked increase of expansion, vital capacity, and ease and fullness of breathing, and strengthen the respiratory murmur while, at the same time, lessening bronchitis. I have always believed that the good results to be got by the various inhalations are due not so much to the drugs inhaled as to the excellent breathing exercises given, a view I am glad lately to see advocated by so good an authority as Denison, and the fact that all of them, however various the mixtures used, gave good results while uniting in but one common feature, the deep inspirations necessary, would seem to uphold this view.

Such, then, are the chief non-medical measures at our disposal in the therapy of consumption. I do not bring to your attention to-day any of these strategies or new. Their virtues have been written of often before, but they have not won the attention which the complete trial their merits deserve.

Behind us lie innumerable cases cured with gradually increasing doses, a few good, and a few bad, cases cured with most utterly valueless remedies, and a few better cases cured by means before us, but a few others cured by the application of serum therapy, and a few better cases cured by the experimental stage. To neither drug nor serum would I deny virtues. I use them with good effect, and I believe

cases, but with every added year grows the belief that as the basis and foundation of a rational treatment of pulmonary tuberculosis must lie an intelligent and persistent application of hygienic, dietetic, and, if possible, climatic measures. That they will demand much patience and attention on the part of the physician is no argument against them. Knopff, in an article in the *Medical Record*, in February, 1897, well puts it, when he says, referring to such measures, "They can be carried out by any physician in private practice whose patient is willing, obedient, and so situated as to have all the comforts and surroundings which hygienic and dietetic treatment demands"; and even if in our great cities there are many patients whose means makes it difficult to procure for them all the advantages we could wish, yet even here one great blessing of the method appears, that given a proper perseverance there is no other treatment so many of whose features are so reasonable and inexpensive.

I do not stand here to-day as a Nihilist in medicine, denying any efficacy to drugs; no man realizes their value more than I, and no one is more willing to confess their utility, when judiciously used, or to avail himself of them as adjuvants. My contention is that they are not always judiciously used; that it is too often forgotten that no drug, whatever its virtues, which upsets the stomach, destroys the appetite, or creates a disgust, can, or ever did, do good.

I have no doubt that I will be told that creosote has been given with good effect in large doses. I myself have had patients with stomachs so hardy that they could tolerate thirty drops or more at a dose, but such patients get well as much or more because of their wonderful stomachs than from the effect of the drug. I know that cod-liver oil in those whom it does not nauseate is the most admirable of foods, but with what percentage does it fully agree? I know that cough syrups with morphine will control a cough, but at what price?

On the whole, I have not been able to convince myself that the majority of cases can tolerate more than three to five drops of Morsani's creosote, not always that much, give it as you will—in milk, in capsules, pill, whisky, or gentian; that oil will be assimilated without nausea by most consumptives, or that the lessening of the sweats which atropine produces is more than of temporary value.

Bitter tonics, or orexine, for those who can afford it, will create a fictitious appetite for a few days, but disappoint us in the long run. Fever medicines will bring down the temperature, but the cause is not removed, and it will rise again as active as ever; morphine will control the cough, but it paralyzes the vitality of the protoplasm, whose activity is our patient's salvation, and its effect are but fleeting and deceptive. Medicines galore are, and have been, recommended; each has had its enthusiastic advocates, nearly all, after a longer

or shorter course, have again sunk into innocuous desuetude—and why?

Because no man can treat phthisis long and not realize that nothing which in the least degree upsets the stomach, that very citadel of the consumptive's defenses, can, whatever its theoretical advantages, be anything but a curse to his patient.

The only valuable results are those which will last, which are based on a vitalizing of the whole system, a stimulation of metabolism, on a strengthening of the cells to oppose the invader; the thing to be attacked is not so much the lesion in the lung directly as the lowered vitality of the body and the deficiency of appetite, and drugs directed to a conquering of the bacillus *in situ* are not to be compared with measures which enable the organism itself to acquire strength to overcome the disease. These things can be brought about best in two ways: by an improvement of nutrition, which must, after all, come from the stomach, and an increase of the amount of oxygen taken into the lungs.

Air and Food.—Those are the drugs to which we can always trust. They will never deceive us, if our patient can be taught to get both in good amounts; not necessarily the air of our climatic resorts, splendid as it is, and wonderfully as it can help us in our work. There is good air, if not the best, all around you, if you can but teach your patient how to take it in; wherever good sunshine goes are possibilities for health; wherever food can be enjoyed and assimilated there is hope of cure.

Throw away two thirds of your medicine bottles and use the other third less often; carry out a hygienic plan of life. Even if your patient can not leave the city for the purer air of the mountain heights, stimulate the appetite by Nature's appetizers, air and exercise, which alone are permanent in their results, and which are as superior to gentian and nux and quassia as sunlight is to darkness. If he can get away to a better climate send him by all means. In that higher, purer air he will have an aid in his struggle which can not be overestimated, and whose beneficent results I in my own case have felt.

But if he can not, if he belong not to the upper ten, but to the submerged million, if he must stay where he is, do not let him lose hope; teach him how to live; remember what are the bosom friends of phthisis—darkness, dampness, want of air. Fight these, move his quarters till the sun can peep in and bring him health, till, under the eaves, if need be, he escapes the miasm which rises from the damp subsoil, and see that he has the cubic air space which science has taught us to demand. Teach him how to use his lungs, widen the narrow chest, stimulate the sluggish skin, and regulate thereby the unbalanced circulation, bring into play all those natural recuperative forces which he has neglected, or never known; then will the appetite and the spirits begin to return; then will the color of health replace the

hectic flush in his cheeks; then will the lesions in his lungs clear up, or cicatrize, or calcify, and he will live to bless you.

65 FRENCH BROAD AVENUE.

SOME REMARKS ANENT FACTS NOT FOUND IN TEXT-BOOKS.*

By W. PEYRE PORCHER, M.D.,
CHARLESTON, S. C.

THE first point to which I would ask your attention is the extraordinary frequency with which deformities of the septum, abnormal growths, and obstruction to respiration, even to partial or complete closure of one nostril, are found, while the patient is entirely unaware of the existence of such obstructions or abnormalities. To be more explicit, I am sure that you have all, like myself, commonly found projecting from the septum a shelf of cartilage extending clear across to the opposite turbinate, the sharp and hard edge of which is pressed up against or actually sticks into the mucous membrane; or from old adhesions the outer wall of the nose or mucous membrane of the turbinate may be partially or completely adherent to the septum; or there may be polypi or other tumors, of the presence of which the patients will express complete ignorance, and in some instances they will with difficulty be induced to put credence in the statement of the physician that such conditions actually exist; or he may be met with the astonishing reply that if such conditions really exist they have become quite accustomed to their presence and do not wish their removal. I have found that in many instances this is one of the chief obstacles which one has to contend against in laryngology, unlike ophthalmology, where the least irritation about the eye causes the patient to rush to the operator for relief; but not so with the otologist and rhinologist. We are told that incipient deafness, marked obstruction to respiration, and very considerable hoarseness are only natural characteristics peculiar to the individual, and should not be meddled with.

I will illustrate this with two typical cases very common in everyday practice among specialists: The patient was a young lady in whose left nostril there was a deflected septum, and an echondrosis or cartilaginous shelf projected across the nostril and into the opposite turbinate. Being aware of some irritation, the cause of which she knew not, she had picked a hole through the septum in the effort to rid herself of it. She was immensely surprised when I told her of the presence of this shelf of cartilage. After its complete removal and the restoration of the normal calibre of the inferior meatus, she remarked to me that she felt a great draught through the nose, to which she was unaccustomed, and

that she intended sending her whole family down to me, thinking that perhaps they might have a like condition. It has always amused me to hear the remarks made by different individuals after the removal of these growths, and obstructions to normal respiration. One man said, with a long-drawn breath, "Why, I can breathe upstairs and downstairs!" A former Episcopal bishop of this State said, "Why, I can breathe down in my boots!" A young married man said he could sleep so soundly that the baby could not wake him up. Another said his sight was improved so much that his glasses were getting too strong for him. A young lady said that she got so much air through her nose that it frightened her, and many persons have said they were wonderfully improved. In every instance it has been hard to convince the patients that these conditions existed, even though the obstruction may have sufficed to cause complete closure of one nostril. Of course, the atresia of the nostril has been so gradual, owing to the slow growth of the tumor, that the patients have become accustomed to the limited breathing capacity, and they are actually surprised when the normal calibre of the nose is restored.

The next cases were those of several girls in a family who were the victims of incipient deafness. They were found to be all mouth breathers of a marked type, and large adenoids in the vault of the pharynx were present. The external ears were partially filled with impacted cerumen and aspergilli. They had been much addicted to salt-water bathing, and especially fond of diving. I informed their parents of the condition of the ears and urged the necessary operations. I was amazed when I was told by the father that the deafness was natural to them, and that he did not wish any operations or interference whatsoever.

I could cite numerous other cases illustrating these facts, but these are typical cases and suffice to show my meaning. The evident explanation is, that persons become so accustomed to limited respiration, slight deafness, nasal atresia, and subacute laryngitis that they will almost or completely ignore their presence, and even when these abnormal conditions are pointed out to them they will in some instances prefer anything short of total disability to operative interference of any kind. This forms a very serious obstacle to the carrying out of proper preventive measures in the treatment of incipient diseases of the upper air passages.

The next point that I would allude to is the inability of patients to blow pus out of the nose when it has accumulated and been accumulating for so long that the inferior meatus is filled with pus. Of course, this is only found when one or other of the accessory sinuses has been continually overflowing with pus, but from some cause or other the patients are unable to blow out the pus and the accessory sinuses always partially filled. This occurs so rarely that it can not be attributed to ignorance or stupidity on the part of the patient. The fact of its long continuance, in young subjects es-

* Read before the American Laryngological Association at its twenty-third annual congress.

pecially, would constitute a strong factor in the final atrophic degeneration of the contiguous surrounding tissues. I have always been at a loss to understand this inability of the patients to blow pus out of the nostrils. Even with the aid of the spray or douche, unless the patients were very carefully trained, the nose would often remain more or less bathed with pus and mucus. The explanation appears to be that the discharge reforms so rapidly that the patient finds it impossible to remove it. Frequently before atrophic degeneration has greatly advanced, the calibre of the nostril has become so narrowed by the tumefied turbinates, or rather the space between the turbinates and the septum is so small, that the pus is retained above even when it is blown out below, so that persistent cleansing of the nostril is required to maintain patency.

I am not aware that these points have already been touched upon in the text-books or brochures, or, if so, they have escaped my attention, but they occur so generally that I have thought them worthy to ask your attention to them.

A CASE OF

FRACTURE OF THE NECK OF THE FEMUR.*

By FIELDING LEWIS TAYLOR, M. A., M. D.

BRIDGET H., aged forty-five years, single, housekeeper. This woman attempted to board a bridge train on the evening of November 12, 1895. She says the guard shut the gate just as she was stepping on, and that the train moved off, throwing her to the station platform.

I first saw her at her home on November 13th. There was loss of function of the right lower extremity, eversion of the foot, prominence of the hip, swelling and pain on pressure in Scarpa's triangle, and marked crepitus, but no shortening at that time, although it appeared later.

She was treated until December 18th on a firm bed with Buck's extension and lateral sand bags, the external one extending from the axilla to the foot. A weight of about ten pounds was used in the beginning and gradually lessened to about four. When the extension appliances were removed no crepitus could be made out; there was a large callus and some abnormal mobility of the shaft.

A plaster case was applied to the entire limb for two weeks longer. When the cast was removed union was firm. There was some peri-arthritis of the knee due to the long-continued strain on the ligaments in a rheumatic subject. Under massage, nutrition and function gradually improved. The patient was provided with crutches and encouraged to use the limb. After about two months she used only a stick, which was discarded later.

Examination now shows slight prominence of the trochanter, shortening of about an inch and a half, normal flexion, inversion, and eversion, while the patient walks with scarcely a perceptible limp and experiences no discomfort, although she is at times on her feet for

many hours together. While the late appearance of the shortening would seem to indicate a fracture of the small part of the neck, from the bony union, the large callus, the marked crepitus, and the excellent functional result, I take it that the femur was broken at the base of the neck.

During the long confinement to bed careful attention was paid to the general condition by means of sponge baths and massage.

SOME CRITICAL AND DESULTORY REMARKS ON RECENT LARYNGOLOGICAL AND RHINOLOGICAL LITERATURE.

By JONATHAN WRIGHT, M. D.

(Eighth Paper.)

IN a few years even the most important medical monographs have ceased to attract attention, and the vast majority of them have ceased to deserve it. It is nevertheless true that in the enormous flood of such productions many a valuable scientific observation, many a subtle suggestion, many an accurate deduction is lost sight of, sometimes temporarily, but usually forever. It is a lamentable fact that, with a very few exceptions, our medical writings are as devoid of literary grace of composition as the hieroglyphs on Egyptian tombs. Dreary stretches of disjointed clauses and of uncouth and wonderfully compounded words of ancient or foreign derivation overwhelm the mind already burdened with the attempt to grasp an unfamiliar fact or idea. It seems as though our facts, in order to acquire weight, were laden with ponderosity of statement. Goethe makes Mephistopheles in the guise of Faust say to the pedantic student:

"Wer will was Lebendiges erkennen und beschreiben
Sucht erst den Geist heraus zu treiben."

As Goldsmith said to Johnson, our little fishes talk like whales, and this is a habit which is easily acquired and hard to escape from. Occasionally a distinguished medical author will write a popular scientific paper for the lay reader, and it is then ludicrous to observe how the leviathan of the deep flounders in shallow waters.

It might seem that perhaps we should seek an explanation of our difficulties as readers in our own mental equipment, for Goethe, with equal wisdom, elsewhere says: "Whoever is about to accuse an author of obscurity should first scrutinize his own understanding to see if everything there is perfectly clear. In the twilight even plain print is illegible." This is a retort which is more applicable to the individual critic than to the totality of reading humanity.

The nature of a medical topic may not equal in interest that of a tale

"Of moving accidents by flood and field,
Of hairbreadth 'scapes—"

but the driest and most intricate subject may be illumined by the light stroke of a skillful hand. The par-

* Presented before the Society of the Alumni of the City (Charity) Hospital, November 9, 1898.

liamentary tactics of the eighteenth century are as prosaic a subject as can be found in English history, but in the glowing lines of Macaulay's essays they assume an absorbing interest even to the casual reader. It is doubtless true that such power is a heaven-bestowed gift and a faculty not to be acquired at the wish or the effort of the average medical essayist. Nevertheless, a little care, a little extra labor, and perhaps a little time spent outside the narrow domains of purely medical literature would give many a medical essay wings for a more prolonged flight than is usually the case.

Medicine is not an exact science, and much of the ambiguity of its literature may be considered due to the uncertainties and doubts which are inherent in its theses, but the existence of a doubt is no reason why the terms of the doubt should not be clearly stated. From time to time there is an agitation for a universal scientific language. The idea is, of course, utterly impracticable—"such stuff as dreams are made of"—but were it established our present dreary literature would be still more unbearable, for we would then be writing in a foreign language. Virchow has lately delivered in London an address which has justly excited the admiration of the scientific world, but not so much on account of the intrinsic value of the matter which it contained as by the fact that this learned man was able to use a foreign tongue to express his thought. It can not be denied that this was admirably done; but turn for a moment to his lectures on cellular pathology and morbid tumors, written, some of them, more than forty years ago, and the difference will at once be seen between the foreign tongue and the native idiom. By attentive perusal of the English speech the speaker's ideas may be grasped, but in his German lectures the thought flows into one's consciousness without apparent mental effort. It may be said that in reading the *Cellular Pathology* and the *Morbid Tumors* now we are going over familiar ground, while his Charing Cross lecture is comparatively unfamiliar. Proceed to read precisely the same familiar principles in regard to morbid growths laid down in the first ordinary text-book of pathology which comes to hand. Soon our minds are benumbed with fatigue and our eyelids weighed down with sleep. If this is so in regard to familiar subjects, how much more severe is the mental effort to grasp a new and perhaps an important idea from the involved and tortuous phrases of much of our medical literature! Is it any wonder then, as I have said before, that many an important fact, many an accurate deduction, is lost in the turbid flood when it should sparkle with a brilliancy borrowed from the stream?

The title which I chose for these papers several years ago and the forbearance of the editor allowed me to be a little discursive in my remarks. I started to write what has preceded as a preface to a review of a work which had escaped my attention at the time it was published in 1895, and which I have lately read with per-

haps a keener appreciation, because the recent trend of rhinological thought has gone to prove that much in the work is of value and deserves an attention which it has not received, so far as I am able to judge. I hasten to say, lest it be thought that I have, had this work in view in my foregoing remarks, that it forms a refreshing contrast to much of the recondite literature, especially the German literature, of the subject. It is written in especially clear and forcible language. I refer to the work of Harkne: *Beiträge zur Pathologie und Therapie der oberen Athmungswege*. In the study of the pathology of the nose the rhinologist labors under exceptional, almost unique, disadvantages. In the first place, the topography of the region is complicated and difficult to understand without the help afforded by constant demonstration on the cadaver. Unfortunately, it is precisely that help which it is so difficult for the rhinologist to obtain. Frequently his only conception of the gross anatomy of the parts which he treats is derived from scanty reference in general or special text-books, from the shadowy and indistinct recollections he has of having once or twice in his student days seen a head sawn open in the dissecting room, and from the innumerable but monocular glimpses afforded by anterior and posterior rhinoscopy. This scanty anatomical study is due not so much to neglect as to absence of opportunity. Even where the student is compelled to make sections of the head in the dissecting room, which is now fortunately the case in most schools, the variations in the configuration and relationship of important parts are so great that a large number of specimens must be carefully studied and compared before a full knowledge is obtained of the anatomy of the internal nose. This is manifestly impossible in anything but a post-graduate curriculum. Study of the internal nose in the post-mortem rooms of our hospitals is attended by great difficulties. The greatest obstacle to be overcome is the technical one of gaining admission to the cavities of the nose without the disfigurement of the face of the subject. While in this our beloved land the laity has not an especially great respect for the sanctity of human life and social privacy, it has a great regard not only for the lives of dogs and cats, but for the sanctity of the human cadaver. Even when

"He's only a pauper whom nobody owns,"

we do not dare in the post-mortem room to disturb the features of the dead. Harkne's method of making the examination to some extent obviates this difficulty, and should be studied by those having opportunity to make use of it. But even if we had free access to the post-mortem room and the free use of the cadaver, which would afford us opportunity for perfect familiarity with the normal anatomy of the parts, there is still another very great difficulty in the study of the pathology of nasal disease. Nearly all the problems with which we as rhinologists have to deal are found in those nasal

affections which do not result fatally. The examination of the nose in a subject who had died of nasal sarcoma would not be very instructive, but if we could follow our cases of atrophic rhinitis through a portion at least of their clinical history to the autopsy table, and there make numerous and careful examinations of the mucous membrane and bony structures of the whole intranasal tract, it is very possible indeed that much of the obscurity which enshrouds the etiology and pathogenesis of this distressing malady would be cleared away. It can scarcely be doubted that to these manifold difficulties we owe the lamentable fact that the development of our knowledge of the pathology of the internal nose lags far behind that of almost every other organ in the body. To Zuckerkandl, the Fraenkels, Dmochowski, and Harke rhinologists owe a debt for what they have done in supplying us with much of the exact knowledge of nasal pathology which we possess.

Harke, in the first place, calls attention to that very frequent form of nasal obstruction due to the lack of function of the external muscles of the nose which results in the collapse of the alæ. In our endeavors to make a straight septal wall out of a distorted quadrangular cartilage we frequently fail in the chief end we should have in view—i. e., to reestablish proper nasal respiration. This purpose is frequently defeated by the flaccidity of the alæ nasi. Harke rightly says this condition is frequently seen in city dwellers, and quite aptly calls their noses "dead noses." It is perfectly useless to remove a posterior nasal spur if we have no hope of removing an anterior nasal paralysis. Dr. Myles and others have invented nasal dilators to overcome this difficulty, but as yet they have not proved very efficacious for various reasons, although Harke speaks approvingly of the one known as Feldbausch's. I see no reason why in these cases a great deal might not be done by nasal massage, by the use of the faradaic or galvanic current, and by automatic exercise of the nasal muscles. In some instances, however, there has seemed to me to be hopeless paralysis if not atrophy of the external nasal muscles. Far too little attention has been given to this subject. It is a very frequent condition existing alone and still more frequent as complicating internal forms of obstruction, because in the latter we are apt to have paresis and atrophy from long-continued disuse.

Harke says that in his dissections he very frequently found the mucosa of the nasal chambers very severely inflamed, while that of the accessory sinuses was entirely normal, showing, as he believes, that in spite of the direct anatomical continuity of structure pathological processes heitate to pass from the former to the latter region. I think it was Bo-worth who, several years ago, pointed out this fact in regard to inflammation of the nose and throat, saying that there is an appreciable interval of time in the involvement of contiguous regions.

Harke speaks in a suggestive way of the usual method of blowing the nose while the nostrils are compressed. I must confess that while I can readily understand how an augmented intranasal air pressure may dilate the openings of the accessory cavities and of the Eustachian tubes, I can not bring myself to believe that very much fluid can enter these closed cavities if it is of the usual consistence of the nasal mucus or more viscid than the normal fluid. When, by means of the intranasal alkaline douche, we have washed away and diluted the usual secretions of the parts, it is doubtless a fact that this action may follow forcible blowing of the nose, to the possible injury of the mucous membranes of those cavities. In fact, sad clinical experience frequently reminds us that this danger is not a fanciful one. On the other hand, it is also easy to understand how an unobstructed blast of air past these openings tends to rarefy the air in them, and to suck out the fluid contents. It is a matter of great importance that the rhinologist should have this principle of physics plainly in his mind when he orders the nasal douche. With the proper directions properly carried out, it is a harmless and indispensable adjuvant of nasal treatment. In studying this question the works of Donders, Bloch, Paulsen, and Franke will be found invaluable.

Harke attempts to explain the discrepancy in the statements of authors as to the relative frequency of the dental and the intranasal origin of the purulent inflammations of the maxillary sinus, by saying that in the former case there results a foul-smelling discharge which does not tend to spontaneous cure, and these are the cases which come under the observation of the clinician. Those cases of *intranasal* origin either recover spontaneously or their symptoms after a time become insignificant, and they are not compelled to seek relief. It will be remembered that E. Fraenkel and Dmochowski found post mortem a large percentage of cases in which the maxillary sinus was diseased, and in which during life there had been no sign of it. They claimed that much the larger proportion of these cases gave no evidence of the disease having been of dental origin. Harke makes the sententious remark: "Carious teeth and antrum suppuration frequently dwell beneath the same roof without ever having made one another's acquaintance." He found food in the antrum after death when violent emesis had immediately preceded dissolution. Particles of tobacco were found in the antra of snuff takers, and he suggests this as a cause of suppuration in some cases. I have seen snuff particles in the discharge from the external wound of a frontal-sinus case addicted to the habit, but I am uncertain if this was the primary cause of the affection. Harke's belief in the rarity of the direct extension of inflammation from the nasal to the accessory cavities is based on his experiences derived from autopsies. His statements are interesting when he declares that the accessory sinuses are not only frequently found uninvolved

in cases of diphtheria and croupous inflammation of the nose, but that in chronic ozæna the same observation may be made. Such direct observations tend to refute the claims advanced a few years ago by many writers that sinus disease is the frequent if not the constant cause of ozæna in atrophic catarrh.

I am not prepared to accept the statement that the irritation of mucopurulent secretion from the accessory sinuses in adults is the frequent cause of lymphoid hypertrophy in the nasopharynx and oropharynx. There seems to be more plausibility in his subsequent statement in regard to children. In infants the accessory sinuses practically do not exist, for even the maxillary sinus is of insignificant size; but the nasal passages themselves are really small sinuses which open into the nasopharynx, and the mucopurulent secretion from their inflamed mucosa acts, he says, as a constant irritation to the lymphoid follicles in the pharyngeal mucous membrane. This is as much as to say that the inflammation of the mucosa of the nasopharynx and oropharynx is secondary to that of the nasal structures. Although Dr. Jacobi and others also maintain this position, I see no reason to believe that it is essentially the true one. Lymphoid metabolism being so active in infant life, *a priori* it is fair to presume that the lymphoid structures are the first to react to the vasomotor shock which we usually call "catching cold," and I have no recollection of ever having examined the nasopharynx of an infant, however young, suffering from nasal obstruction or "the snuffles" without finding lymphoid hypertrophy, and I have on one or two occasions seen in the pharynx of stillborn children considerable amounts of it. It nevertheless seems extremely probable that both nasal catarrh and nasopharyngeal obstruction in infants react injuriously on one another, and the anatomical relations which Harke points out between the nasal and postnasal regions in children should be kept in mind.

These are a few of the points which Harke dwells on in the *résumé* of his investigations, and there are other valuable hints for the rhinologist to be found in his brochure.

No one can look at the picture presented by the high-power microscopic objective of the atrophic process in the nasal mucous membrane without realizing that he is confronted by a very active process—a process of confusion, a process of metamorphosis, a process of annihilation. The disorderly invasion of fibrous tissue and hordes of round cells into the peaceful realm of glands, blood-vessels, and fibro-elastic tissue; the change of the surface columnar epithelium to the flat horny cells of the integument, and of the curling elastic fibrous tissue into sodden scarlike masses; the destruction of the unstriped muscular tissue, and thereby the abolition of the working power of the contractile blood reservoirs and of the secreting functions of the racemose glands, enable us to realize that there is at work in this tissue

some agency whose power is as great as it is mysterious. The first impression is that this can not be essentially the dying embers of a previously blazing hypertrophic process. However it may have started, it must now receive an impetus which was lacking in that early proliferative stage of hypertrophy. And yet there is no one feature of the process which we do not find amply exemplified in the tissue changes of hypertrophy of the nasal mucous membrane. We have here the cornification of the surface epithelium, but this is also noted in the thickened epithelial layers of the papillary hypertrophies of the inferior and the edematous hypertrophies of the middle turbinated bodies. In the atrophied mucous membrane we find all the stroma crowded with round cells, but in hypertrophy we also find areas of round-cell infiltration. We find that the walls of the blood-vessels are thickened in their fibrous coats, as is also the outside tunic of the glands. We find knobs of the fibrous tissue jutting into the lumina of the blood-vessels and of the glands. We find that this fibrous tissue is compressing circulatory and secretory structures, but all these things are also seen in the hypertrophic process. There is one distinguishing observation, however, which is significant. We miss, in the atrophic process, the glandular and vascular ectasia which are such prominent features in hypertrophy that they are regarded as essential to it. A little study convinces us that these features of the histology of hypertrophy may have been obliterated by the relentless overgrowth of the low-grade fibrous tissue. That this is not simply a process of substitution we know from the fact that the thickness of the mucous membrane has greatly diminished. This is a withering tissue that is being formed in such abundance. It clogs, by its presence, the nourishing blood and lymph channels. It causes the death not only of the more highly organized constituents of the mucous membrane by direct pressure upon them and by cutting off their alimentary channels, but it shuts off its own nutriment and so subsequently brings about its own atrophy. Now this is fibrosis. What in hypertrophy is only one of many processes is here the preponderant if not the sole one. The facts seem easily stated, and the course of events easily followed. The question underlying it all, and the question which interests us practically as rhinologists quite as much as it does in a purely scientific sense, is, "What is the cause of it all?" I imagine it does not make much difference in reality, so far as aetiology is concerned, whether we consider this process as starting frequently or even always in a hypertrophied membrane, or whether we acknowledge that it often or even always starts *de novo*. Before we proceed further, however, we must separate as definitely as we can one set of cases from another. This is to be done by the clinical features they present. In one well defined class, which for convenience we may call the "atrophy of age," we may place those cases unattended through-

out their whole course by the crust formation and the odor which so mark the clinical picture of the class which, again for convenience, we may call the "atrophy of youth." I do not mean to deny that crusts and odor may exist after fifty, or that simple atrophy without either may exist during earlier life, but I would give this name to each class because in the first category people at or after middle life predominate, while in the second younger people predominate. Now let us dismiss from our consideration the first class of cases—"the atrophy of age." There is nothing in the clinical history of these cases and there is nothing in the pathology to make us regard them in any other light than as having suffered from a chronic inflammation of the mucosa, which has resulted in atrophy through the agency of a fibrosis. The process has stopped or is not of sufficient intensity to give rise to the more distressing of the symptoms. If these were the only cases we encounter our wonder at the course of the pathological process would not be aroused. But the second class of cases, "the atrophy of youth," possesses certain clinical and pathological features which cause us to ask the question already formulated: "What is the cause of all this? Where is the *vis a tergo* which keeps this process going? What are its limitations?"

Cholewa and Cordes* have attempted to answer these problems which nasal pathology presents, and have recently published the results of their investigations of the pathogenesis of atrophic rhinitis. They dispose of the many hypotheses which have appeared from time to time by well-considered criticism. They deny an antecedent condition of hypertrophy of the mucosa as a necessity for the beginning of atrophy. They describe the pathological phenomena in the soft parts, and then proceed to a more detailed account of their examination of the bone changes. This part of their work has interested me very much because it falls in line with the results of my own observations of the mechanism of the vascular supply of the nasal mucosa† and of various bone changes. I have attempted to show in the paper referred to how the blood supply to the vascular sinuses in the mucosa is regulated by the apposition of the radical arteries and veins as they lie in the bony canals, the dilatation of the artery diminishing and its contraction increasing the lumen of the vein. Now it is apparent that if this is the principal food channel of the mucosa any interference, such as absorption or blocking of the bony channels in which the blood-vessels lie, must vitally affect the metabolic changes in the mucosa. The authors profess to demonstrate that the bone changes are the primary ones in atrophic rhinitis. In one of these reviews (June 27, 1896) I have shown how in bony cysts of the middle turbinal we have at the same time bone absorption and

bone proliferation going on through the simultaneous and interchangeable activity of the osteoclasts and the osteoblasts respectively. Others have described the same phenomena more fully and more minutely. Now, Cholewa and Cordes, after reviewing this work, go on to show that in atrophic rhinitis bone absorption takes place without the compensatory bone proliferation. They then cite what they regard as satisfactory evidence that the changes in the mucosa are subsequent to and dependent upon the bone changes. They point out the parallel condition of the bone in osteomalacia, and admit that the cause of this peculiar process is not to be found in the bone itself but in some unknown factor. This is one step forward in the explanation of the method, but does not reveal the mystery of the cause. It still remains to be seen if their contention that the disease begins in the bone will stand the light which may be thrown by future investigations. There are many of the clinical facts which tell for the acceptance of this conclusion, not the least of which is the almost universally acknowledged futility of attempts at a radical cure by topical, or indeed by any measures. It would be manifestly unreasonable to suppose that any surface application would materially influence a bone lesion beneath the mucosa.

REPORT OF A CASE OF TUBERCULOSIS OF THE BLADDER, WITH SOME OBSERVATIONS.

By JOHN J. McGRATH, M.D.,

ADJUNCT PROFESSOR OF ANATOMY AND OPERATIVE SURGERY
IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL;
ASSISTANT VISITING SURGEON, COLUMBUS HOSPITAL.

VITTO C., aged twenty-five years. Operated upon at Columbus Hospital. Married; no venereal history. Had "lung trouble" eighteen months previously. For a number of months he had been suffering from frequency of urination, and at the time of admission to the hospital he urinated every half hour or more frequently, the act being associated with pain and hemorrhage. No bacilli were found in the urine. The examination for stone was negative.

Suprapubic cystotomy was performed in June, 1896. The mucous membrane of the bladder was found greatly congested and studded with tubercles; several small ulcers were present at the base. The bladder was drained for about six weeks and washed out daily. The symptoms all disappeared, and ten months after the operation the patient was apparently well and the urine clear.

Tuberculosis of the bladder has heretofore been considered by many simply as a complication of an almost hopeless tuberculous disease of the kidney or genital organs and not amenable to treatment, and they have failed to recognize the fact that at times it is an independent, primary, localized lesion of the bladder which, especially early in its course, is fairly amenable to treatment.

Tuberculosis of the bladder is a condition which,

* *Archiv für Laryngologie, etc.*, Band viii, Heft 1.

† *American Journal of the Medical Sciences*, May, 1895.

no doubt, is often allowed to go unrecognized, particularly the primary, localized cases, they being often diagnosed and treated as cases of simple chronic cystitis, especially if they have been preceded by a gonorrhoeal infection.

We may divide the cases of tuberculosis of the bladder into primary, localized tuberculosis of the bladder, cases in which the disease begins in and remains limited to that organ, and into secondary or complicated cases, those in which the bladder affection is secondary to or complicated by tuberculosis in some part of the genital tract or in the kidney.

As to the ætiology of tuberculosis of the bladder, we sometimes get a tuberculous family history, and we may also get a history of a previous chronic cystitis which, in turn, may have been caused by a gonorrhoeal infection.

The disease is more common in men than in women, yet not very rare in the latter. It is a disease of early and middle adult life, occurring mostly between twenty and thirty-five years of age, although it may occur in children and in elderly persons.

It is well to bear in mind that the kidney frequently becomes secondarily involved by extension of the disease from the bladder.

In cases of primary tuberculosis of the bladder it is rather improbable that the bacilli gain entrance to the bladder during coition with a tuberculous person, although this is less improbable in the case of women.

Bacilli are excreted by the kidney in the urine, and they may thus reach the bladder, or they may be introduced into the bladder by sounds and catheters. No doubt the most common way by which the bacilli reach the mucous membrane of the bladder is through the blood current from tuberculous foci situated in other remote parts of the body. The bacilli having reached the bladder by any means, and especially if its mucous membrane is in an unhealthy condition from any cause whatsoever, particularly if it is in a condition of chronic inflammation following a gonorrhoeal infection, we can readily understand the ease with which a localized tuberculous cystitis may be started up. The presence of tuberculous bacilli in a healthy bladder would not probably of itself set up a tuberculous cystitis.

The secondary or complicated cases of tuberculous cystitis are caused by extension of the disease directly from a tuberculous focus situated in the genital organs, or else from a tuberculous kidney through the ureter.

The bladder is usually diminished in size, often very much so; the walls are much thickened, and the mucous membrane is greatly congested. Ulcers are, as a rule, present, usually in the neighborhood of the ureter or urethral orifices, or occupying the position of the trigone at the base; there are usually one or two large ulcers or a greater number of smaller ones. The mucous membrane usually presents a greater or less number of miliary tubercles studding its surface; thus the

mucous membrane may be simply very markedly congested or ulcerated, or there may be present miliary tubercles in greater or less number.

In secondary or complicated cases we find, in addition to the above, the prostate, seminal vesicles, epididymis, or testes, or one or both kidneys involved in the process.

In both primary and secondary cases there are apt to be tuberculous lesions in other remote parts of the body—for example, in the lungs—and in doubtful cases these remote lesions should be carefully sought for.

Sufferers from this disease are sometimes otherwise fairly healthy individuals, especially those in whom the disease is limited to the bladder and when the disease is in its early stage. Usually, however, tuberculous cystitis is complicated by tuberculous lesions elsewhere in the genito-urinary tract, and in many cases there are evidences of tuberculous lesions in more remote parts of the body.

The history of tuberculosis of the bladder is usually of some duration, varying from six months to several years, and no doubt the bladder may be the seat of a tuberculous inflammation for some time before any symptoms appear to indicate the presence of the disease.

Frequency of micturition, gradually becoming more marked and associated with pain and occasionally followed by the discharge of a few drops of blood, is usually the first symptom. These signs become more and more marked as time goes on, until, in the advanced cases, the urine is voided every half hour, or more frequently, night and day, accompanied by great pain and considerable hæmorrhages, and the patients are unable to sleep or obtain any relief from their almost constant suffering. When this stage in the course of the disease is reached the condition of the patient is almost unendurable, and the general health becomes greatly impaired. If other active tuberculous foci are present, of course they add still further to the misery of the patient.

Rontier divides the course of the disease into two periods—the first up to the time that micturition becomes almost incessant, and the second from that time on.

Examination with sound or catheter is usually accompanied by much pain and hæmorrhage.

The urine usually contains pus, blood, and detritus from the mucous membrane of the bladder, and may be either acid or alkaline.

No doubt tubercle bacilli are usually present in the urine, but it is often very difficult to find them. However, they should be carefully looked for in order to aid in elucidating the character of the trouble.

In making the diagnosis it is necessary to determine whether a given case is primary and limited to the bladder, or secondary and complicated by a similar process elsewhere in the genito-urinary tract. The diagnosis of the secondary cases is often easy if we suc-

ceed in finding evidence of tuberculosis in other parts of the genito-urinary tract. Diagnosis of primary cases is frequently difficult; at times the family history or signs of tuberculosis in other remote parts of the body—for example, the lungs—will excite our suspicions and aid us; but only too often, in these primary cases, the physician limits his investigation to the local conditions and fails to overhaul the lungs, etc., and the result is that these unfortunates are treated for every possible disease and by every conceivable method except the correct one. One should be on the lookout for these cases. All cases of chronic cystitis that appear intractable and fail to respond to our ordinary methods of treatment should receive a thorough examination with the idea of tuberculosis in mind. It is just these cases of primary localized tuberculous cystitis that are most favorable for treatment, and they are the ones that most readily escape our recognition. We often have to make our diagnosis by excluding other conditions which give us very similar symptoms, and that is the case especially if we fail to discover bacilli in the urine.

The symptoms of tuberculosis of the bladder often resemble those of stone, but cases of stone are easily recognized by the sound, and patients suffering from stone, when they remain quiet and recumbent, usually obtain a considerable amount of relief. Not so with tuberculous cystitis. The symptoms of tuberculous cystitis above enumerated also resemble rather closely those of neoplasm.

The cystoscope often gives us considerable help, but not so much as one would expect at first thought. In the first place, the cystoscope is usually very painful to use in tuberculous cystitis; and, secondly, the fluid in the bladder in tuberculous cystitis is cloudy and bloody, and, although the bladder is well washed out before examination, the bleeding is apt to continue and thus obscure the view. In women the urethra may be dilated, and through it the examination of the bladder made with the finger.

One should not forget that a gonorrhoeal cystitis may become tuberculous, especially if it is neglected, or if there is a tuberculous deposit elsewhere in the body, or by the use of infected instruments.

In cases of doubt, and they occur with the best diagnosticians, one should not delay too long with an exploratory suprapubic cystotomy, especially if the symptoms are pressing.

Within the last few years cases of tuberculosis of the bladder have been treated, and with success, by making a suprapubic opening and draining the bladder, and this procedure seems to me, at least for most of the cases, probably all the primary cases, not only justifiable but proper.

In the primary cases this operation offers a very good chance of complete cure; and even in the secondary or complicated cases the result, as evidenced by some of

the cases reported by others, is often very satisfactory—cure of the bladder lesion being obtained, the distress and hemorrhages from the bladder relieved, and an opportunity thus afforded to recuperate by rest, feeding, general medication, etc.; the tuberculous processes in other parts of the body may indirectly be brought to a standstill, and at times, even in what would seem almost hopeless, secondary, complicated cases, we are able to effect a cure. Several such cases have been reported. The great point is to make the diagnosis early before the kidney is involved, and not to wait too long with other methods of treatment, because the kidneys, one or both, will finally become involved by extension of the disease, and then this radical method of treatment by operation gives us much less satisfactory results.

Even when one is not certain of the diagnosis the operation will clear it up, and is still the best means of relieving similar symptoms due to other causes, as, for example, stone, tumor, foreign bodies, etc. Further, in late cases it is wise to operate to relieve the misery of the patient, even where there is no hope of curing the disease. The dangers from the operation itself are small.

The operation cures by securing rest to the bladder, and it gives the surgeon the best chance to treat the mucous membrane locally.

As the ulceration is almost invariably at the base of the bladder, the suprapubic has many advantages over the perineal operation; the interior of the bladder can be inspected with ease through a suprapubic incision, and the retention of a drainage tube in a suprapubic wound is attended with much less suffering than in a perineal wound. In women the suprapubic operation has many obvious advantages over the formation of a vesico-vaginal fistula.

Some surgeons recommend, in the early stages of the disease, treatment of the general condition of the patient and the regular irrigation of the bladder with various antiseptics, etc., and do not believe in operating until later, when micturition has become almost incessant and accompanied with great suffering; then it is often too late to operate with any other hope than that of ameliorating the sufferings of the patient. The kidney is usually involved by this time in the tuberculous process. The operation should not be delayed too long, especially if there is no improvement under less radical methods.

The operation is done with the patient preferably in the Trendelenburg posture: the tubes are introduced into the bladder and held fast to the edges of the wound with a silk stitch. The fistula should be left open and the bladder washed out daily with some mild antiseptic solution until the urine clears up, and this may take weeks or months, when, as a rule, the fistula closes spontaneously.

There are different views as to the treatment of the ulcers at the time of operation; some use the eurette, some perfor the Paquelin, still others rub in iodoform.

It matters little just which one of these procedures is followed. Bardenheuer removed all of the mucous lining of the bladder in three cases; but this seems to be rather unwise, as, aside from the serious element of danger it adds to the operation, it is always questionable whether one gets all the diseased tissue away, and the cases which have not been treated so radically seem to have done very well. Of course, one should attend to the general health by the use of proper diet, tonics, etc., both before and after the operation.

A tuberculous lesion elsewhere—for example, in the lungs, the bones, etc.—is not, in most cases, a counter-indication to the operation, although in advanced cases of pulmonary tuberculosis, etc., the patient should not be operated upon unless his condition is unendurable, owing to the frequent and painful micturition and loss of sleep, etc., when operation may be resorted to as a palliative measure.

In primary cases we have a good chance of cure by operating, especially early; and even in secondary cases, in which the original focus is in some of the genital organs—prostate, testes, etc.—the results are often very good.

In those secondary cases in which the primary lesion is in the kidney the prognosis is but poor unless the process involves but one kidney, and this can be removed or drained, leaving the second kidney healthy.

148 WEST FORTY-EIGHTH STREET.

Therapeutical Notes.

Collutories for Infantile Aphthæ.—The *Gazzetta degli ospedali e delle cliniche* for November 29th gives the following formula:

1. R Sodium borate 4 parts;
Tincture of myrrh 8 "
Syrup of mulberries 60 "

M.

2. R Borax 4 parts;
Tincture of benzoin 2 "
Distilled water 10 "
Syrup of honey 20 "

M.

3. R Calcium chloride 3 parts;
Honey 20 "

M. The patches are to be touched four or five times a day with a camel's hair pened dipped into either of these mixtures.

An Enema for Membranous Enterocolitis. We find the following formula in the *Progres medical* for October 1st, taken from the *Revue medicale de la Suisse romande*:

- R Quince-seed mucilage 7,500 grams;
Bismuth subnitrate, λ 150 "
Bismuth suboxide, λ each, 150 "

M. After purgation with castor oil, this enema is to be administered. It should be retained for twenty-four hours if possible.

The Use of Mercurial Ointment Internally in Syphilis.—Silberstein, of Hamburg (*Therapeutische Monatshefte*, July; *Wiener klinische Rundschau*, November 20th), considers this treatment much simpler than that by inunction and equally efficacious with the painful injection treatment. He gives the following formula:

- R Mercurial ointment 22 grains;
Powdered licorice 75 "
Glycerin 5 drops;
Mucilage of gum arabic a sufficiency.

M. Divide into sixty pills. Two to be taken twice a day. The mouth must be kept scrupulously clean. After a week or two the use of the pills is to be resumed. [We are not told how long it is to be continued at first, but presumably it is till the sixty pills have been taken, a period of fifteen days.] During the treatment fatty food may be eaten freely.

Hyperchlorhydria.—Boas (*Gazzetta degli ospedali e delle cliniche*, November 24th) recommends the following:

- R Sulphate of sodium 450 grains;
Sulphate of potassium 75 "
Chlorate of sodium 450 "
Carbonate of sodium 375 "
Biborate of sodium 150 "

M. A spoonful in hot water to be taken in the morning.

Lactic Acid in Gynecology.—Daleché (cited in the *Gazette hebdomadaire de médecine et de chirurgie* for December 1st), on the theory that lactic acid is the natural antiseptic of the vagina, has made use of it in leucorrhœa, in the form of this solution:

- R Lactic acid 3 parts;
Glycerin 100 "

M.

Tampons soaked in the solution are packed in the vagina. He reports good results.

A Prescription for Aortic Palpitation.—We find the following in the *Clinica moderna* for November 23d:

- R Quinine hydrobromide 60 grains;
Powdered digitalis, λ each, 30 "
Extract of convallaria, λ each, 30 "

M. Divide into forty pills. From two to four to be taken in the course of twenty-four hours.

The Treatment of Trigeminal Neuralgia.—The *Wiener medicinische Presse* for December 4th (*Klinisch-therapeutische Wochenschrift*, December 11th) attributes the following formula to Hirschkron:

- R Phenacetine, λ each 15 grains;
Antipyrine, λ each 15 "
Quinine sulphate 15 "

M. Divide into six powders. One or two to be taken daily.

Treatment of Exophthalmic Goitre. According to the *Revue médicale* for December 28th, Kant recommends the following:

- R Sulphate of dulcousine 1½ grain;
Water 30 minims

M.

To be taken twice or three times daily. The author quotes a case in which the treatment continued for three months produced a marked diminution of the phenomena of the disease. The drug, however, occasionally produces somnolence and inebriety.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON AND COMPANY.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JANUARY 21, 1899.

A PROPOSED PACIFIC COAST MEDICAL ASSOCIATION.

In the December number of the *Pacific Record of Medicine and Surgery* there is an editorial article in which the writer advocates the formation of a society representing the medical profession of California, Oregon, Washington, Nevada, and Arizona. He states that neither the California State society nor the San Francisco society is so large or so well attended as it ought to be. The physicians of the Pacific States, naturally, are unable to attend a meeting of the American Medical Association in any considerable number unless the meeting happens to be held in one of those States, for they are to some extent isolated. We are not sure that they are much worse off in this respect than those of the Eastern States, though it must be conceded that the association holds its meetings less often in the Pacific than in the Atlantic States.

Much good work has been done by the various Tri-State associations and by organizations which, like the Mississippi Valley Medical Association, draw their membership from a territory larger than that of any three contiguous States, and yet not so enormously large as to make it seriously inconvenient or very expensive for members to attend the annual meetings. As a general thing, of course, the meetings of the American Medical Association are held in cities that are readily accessible from all parts of the country, save the Pacific slope, and that association presumably will always remain the organization to which the profession will look for work of a national scope. It is not to be wondered at, however, that our colleagues of the Pacific States feel their isolation in society matters that do not call for consideration at the hands of the entire profession of the nation. We can well understand, therefore, that they should look favorably upon our San Francisco contemporary's proposal.

SUGAR AS AN OXYTOIC.

Four or five years ago Bossi employed sugar as an oxytocic in eleven cases of uterine inertia, and in all but one with favorable results (*Revue internationale de bibliographie médicale, pharmaceutique et vétérinaire*,

April 25, 1894); so that its use as a uterine stimulant is not quite a novelty. However, the ecboic properties of sugar have recently been studied anew by Keim, a Paris hospital interne (*Presse médicale*, November 9th), and some account of his observations is likely to add to our knowledge of the matter.

Keim's experience has been with sugar of milk. He reports the cases of three primiparæ and two multiparæ in labor at term and a case of incomplete abortion. In all of them the lactose appeared to exert a favorable influence on the progress of parturition. Keim finds, however, that lactose does not act as an oxytocic unless labor has already really begun; it does not originate uterine contractions. The minimum dose employed by him was five drachms, and smaller doses he regards as less effective; on the other hand, he has found no advantage in giving more than six drachms, but thinks it better to repeat the small dose than to give a larger amount at once. The further the process of labor is advanced the more decided is the action of sugar, and it seems to act more effectively in multiparæ than in primiparæ. It begins to act in from ten minutes to half an hour after its administration as a rule, but in some cases the initiation of renewed uterine action is delayed for an hour or two.

Lactose is said to have no influence on the expulsion of the placenta or on uterine retraction—at least, no such action was observed in Keim's cases—and not to augment post-partum diuresis or hasten or increase lactation. Keim believes that sugar acts as an oxytocic only so long as there is something contained within the uterus, for in the case of incomplete abortion which he reports the action ceased as soon as the placenta had been driven into the cervix. It exerts no deleterious influence on the fœtus. It seems to act, not only on the uterus, but also on the abdominal muscles and, indeed, on the muscular system in general; it is, therefore, not only an oxytocic, but also a true stimulant, a tonic which at the same time rouses the muscular energy and hastens the expulsion of the fœtus.

MINOR PARAGRAPHS.

THE INCINERATION OF GARBAGE IN HAMBURG.

At a recent meeting of the German Society of Public Hygiene, Meyer (*Tribune médicale*, December 21st) described the system employed in Hamburg for the cremation of garbage. It applies to the central part of the city, occupied by about half the population. The works consist of thirty-six Horsfall furnaces. The material to be burned is delivered in sealed metallic receptacles. Combustion is promoted by forcing warm, dry air into the furnaces. This is found to be superior to the Eng-

lish practice of employing steam. Except for kindling purposes, no adventitious fuel is required; the combustion is complete. The heat generated is turned to account in operating dynamo-electric machines for illuminating and other purposes.

LEGAL SERVICES FOR THE STATE HOSPITALS.

DISCUSSING Governor Roosevelt's recommendation that the attorney-general's office should do the work now done by special counsel for the individual lunatic asylums of the State of New York, and the offices of these special counsel abolished, the *Sun* suggests that a sensible way would be to employ local counsel when their services were required, and pay them what such services were reasonably worth.

THE NEW YORK RED CROSS HOSPITAL.

THE *Sun's* account of the opening of this new hospital, in West Ninety-third Street, contains this statement: "No cases will be treated where alcohol has contributed to the sickness." In carrying out this provision the medical officers will have a fine opportunity for the retrospective study of aetiology.

MICE AS A CAUSE OF SYMPTOMS OF ILEUS.

DR. WILHELM FRITZ, of Bischofsheim (*Münchener medicinische Wochenschrift*, 1898, No. 52; *Deutsche Medizinisch-Zeitung*, January 5th), relates the case of a child three years old, that had shown all the symptoms of ileus, but was freed from them by passing two dead mice as the result of a deep enema and a dose of castor oil.

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 14, 1899:

DISEASES.	Week ending Jan. 7.		Week ending Jan. 14.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	15	12	17	3
Scarlet fever.....	152	4	161	12
Cerebro-spinal meningitis.....	0	1	9	1
Measles.....	127	8	170	7
Diphtheria.....	166	31	192	30
Croup.....	13	7	21	7
Tuberculosis.....	180	177	203	147
Small-pox.....	1	0	0	1
Chicken-pox.....	29	0	45	0

The New York Academy of Medicine.—At the last meeting, on Thursday evening, January 19th, the special order was a paper on Inhibition, by Dr. Samuel J. Meltzer.

At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, January 25th, Dr. U. S. Roberts will report a recent case of tonsillar and laryngeal diphtheria in which antitoxine was employed. Papers are to be read as follows: Tonsillitis in Children, by Dr. H. D. Chapin; and The Treatment of Dysphagia and Cough, especially in Tuberculosis, by Dr. W. Freudenthal.

At the next meeting of the Section in Obstetrics and Gynecology, on Thursday evening, January 26th, Dr.

Paul F. Mundé will read a paper on Torsion of the Ovarian Pedicle.

Marine-Hospital Service Health Reports.—The following cases of small-pox and yellow fever were reported to the supervising surgeon-general of the United States Marine-Hospital Service during the week ending January 14, 1899:

Small-pox—United States.

	Jan. 6.	Reported present.
Catherine, Ala.....	1	1 case.
Collinsville, Ala.....	Jan. 3-8.	2 cases.
Mobile, Ala.....	Jan. 7.	2 " "
Bedford, Ill.....	Jan. 7.	1 case.
Medina, Ill.....	Jan. 7.	3 cases.
Nebraska City, Neb.....	Dec. 12.	3 " "
Nebraska City, Neb.....	Jan. 7.	3 " "

Small-pox—Foreign.

Antwerp, Belgium.....	Dec. 3-26.	19 cases.	6 deaths.
Rio de Janeiro, Brazil.....	Nov. 26-Dec. 2.	8 " "	6 " "
London, England.....	Dec. 17-24.	1	1 death.
Monterrey, Mexico.....	Dec. 28.	1	1 " "
St. Petersburg, Russia.....	Dec. 3-10.	3 " "	

Yellow Fever—Foreign.

Monterrey, Mexico.....	Dec. 30-Jan. 5.	3 deaths.
------------------------	-----------------	-----------

The St. Louis Medical Society.—At the last meeting, on Saturday evening, the 14th inst., the following papers were presented for discussion: A Preliminary Report of the Effects of Ligating the Dorsal Vein of the Penis for Functional Impotence, by Dr. G. Wiley Broome; and Fair Play for the Doctor who Recommends the Specialist; A Hint to Both, by Dr. Robert Barclay.

The City (Charity) Hospital.—Dr. Francis J. Quinlan has been appointed laryngologist and rhinologist to the City (Charity) Hospital.

The Buffalo Academy of Medicine.—At the last regular meeting of the Section in Pathology, on Tuesday evening, the 17th inst., Dr. H. Y. Grant opened the discussion on a paper entitled The Pathology of Catarrhal Deafness, by Dr. F. W. Hinkel.

The Memphis Medical Society.—We learn from the *Memphis Medical Monthly* that officers for the year have been elected as follows: President, Dr. B. F. Turner; vice-president, Dr. Frank A. Jones; secretary, Dr. E. M. Holder; reporter, Dr. Richmond McKinney.

The Medical Society of City Hospital Alumni, of St. Louis.—At the last regular meeting, on Thursday evening, the 19th inst., the following papers were to be read: Remarks upon an Ear and Throat Infection with Subsequent Involvement of the Neck, by Dr. Ernest H. Cole; Some Practical Suggestions in Ear Examinations, by Dr. John B. Shapleigh; The Use of Water in Diseases of the Digestive System, by Dr. John C. Falk.

The Chicago Eye, Ear, Nose, and Throat College.—We learn that Dr. Horace M. Starkey has been elected professor of ophthalmology.

The Degree of Doctor of Medicine, Summa cum Laude.—We learn, has been conferred upon Dr. Henry Newton Hemmenan, of New York, by one of the largest of the German universities.

Society Meetings for the Coming Week:

Monday, January 24. Medical Society of the County of New York, Lawrence, Massachusetts; Medical Club (private); Cambridge, Massachusetts; Society for Medical Improvement, Baltimore Medical Association.

TUESDAY, January 24th: New York Dermatological Society (private); Metropolitan Medical Society, New York (private); Buffalo Academy of Medicine (Section in Obstetrics and Gynecology); Medical Society of the State of New York; Medical Society of the County of Putnam, N. Y. (quarterly); Richmond, Virginia, Academy of Medicine and Surgery.

WEDNESDAY, January 25th: New York Academy of Medicine (Section in Laryngology and Rhinology); New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Medical Society of the County of Albany, N. Y.; Middlesex, Massachusetts, North District Medical Society (Lowell); Gloucester, N. J., County Medical Society (quarterly); Philadelphia County Medical Society.

THURSDAY, January 26th: New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopaedic Society; Brooklyn Pathological Society; Brooklyn Society for Neurology; Roxbury, Massachusetts, Society for Medical Improvement (private); Pathological Society of Philadelphia.

FRIDAY, January 27th: New York Clinical Society (private); New York Society of German Physicians; Yorkville Medical Association, New York (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

SATURDAY, January 28th: New York Medical and Surgical Society (private—annual).

Births, Marriages, and Deaths.

Married.

CLOHESSY—REGAN.—In Buffalo, on Wednesday, January 11th, Dr. Timothy T. Clohessy and Miss Gertrude M. Regan.

KENNARD—WOOD.—In New York, on Wednesday, January 11th, Dr. Louis W. Kennard and Miss Maude Irene Wood.

VILAS—ROUSE.—In Buffalo, on Saturday, January 14th, Mr. Royal Lee Vilas and Miss Bonnie Lillian Rouse, daughter of Dr. Morris D. Rouse.

Died.

BURR.—In Wilmington, Delaware, on Friday, January 13th, Dr. Horace Burr, in the eighty-second year of his age.

CLARK.—In Oswego, N. Y., on Wednesday, January 11th, Dr. Charles C. P. Clark, in the seventy-fifth year of his age.

CLARK.—In Oswego, N. Y., on Monday, January 16th, Mary Bliss Hodges, widow of Dr. Charles C. P. Clark, in the seventy-second year of her age.

DEAN.—In Spartanburg, South Carolina, on Sunday, January 8th, W. P. Dean, son of Dr. George R. Dean, aged sixteen years.

DILL.—In New Orleans, on Monday, January 9th, Dr. John J. Dill, in the forty-fifth year of his age.

RICHARD.—In Georgetown, Delaware, on Friday, January 13th, Dr. Charles H. Richards, in the seventy-second year of his age.

VAN EPPS.—In Schenectady, N. Y., on Saturday, January 10th, Dr. Evert P. Van Epps, in the fiftieth year of his age.

Special Articles.

THE LAW IN ITS RELATIONS TO PHYSICIANS.

By ARTHUR N. TAYLOR, LL. B.

II.

THE RIGHT TO PRACTISE MEDICINE AND SURGERY.

(Continued from page 28.)

No Restrictions except by Statute.—The common law* of England did not recognize the inability of the public to discriminate for themselves between the qualified and the unqualified practitioners of medicine and surgery, and therefore imposed no restrictions upon the free exercise of the art of healing; the necessity of such a restriction was, however, recognized at an early date, and in the third year of the reign of Henry VIII a law was enacted prohibiting any person from practising medicine or surgery in London, or within seven miles thereof, without first being examined, approved, and admitted by the Bishop of London or the Dean of Paul's, who should call to their aid four doctors of physic and, for surgery, other expert persons in that faculty. The statute further provided that no person should practise outside of London and a seven-mile radius thereof without being first examined and approved by the bishop of his diocese, or his vicar-general, similarly assisted, saving those practising under privileges conferred by the Universities of Cambridge or Oxford. Seven years later a charter was granted to the College of Physicians in London vesting in it the right of examining and admitting to practice formerly granted to the Bishop of London and Dean of Paul's.

Other laws relating to the subject were enacted from time to time, but, owing to their character, they were not applicable to the condition existing in the United States, and consequently never became laws here.

Statutory Restrictions in the United States.—In the United States the legislature of each State has authority to prescribe qualifications which must be possessed by those practising medicine and surgery within its borders, and it may be said without exception that the legislature of each State has exercised this right to a greater or less degree. An elaborate treatment at this point of the statutes of the several States would be inconsistent with the size and scope of this work, yet a brief *résumé* will, it is thought, be of sufficient value to the practitioner to justify devoting to that purpose the necessary space.

General Classification of Requirements.—The qualifications prescribed by the several States to entitle one to begin the practice of medicine and surgery within their respective jurisdictions may be generally classed under the four heads following:

1. The candidate must have a diploma from a medical college in good standing, the length of the course being specified in many States, and ordinarily being three or four years. In addition, he must pass a satisfactory examination before a board of examiners, the subjects to be covered by this examination being frequently specified.

This is the rule in Arizona, Connecticut, Delaware, District of Columbia, Florida, Georgia, Idaho, Iowa, Louisiana, Maryland, Minnesota, Montana, New Hampshire, New Jersey, New York, Pennsylvania, South Carolina, and Utah.

* For the distinction between common law and statute law, see Art. i, p. 27.

II. The candidate must pass a satisfactory examination as in the first class, but he is not required to have a diploma from a medical college. In some States of this class the time he shall have spent in the study of medicine is designated.

The following are the States within this class: Alabama, Arkansas, Maine, Massachusetts, Mississippi, North Carolina, North Dakota, Oregon, Tennessee, Texas, Virginia, Washington, and West Virginia.

III. The candidate may either present an acceptable diploma or, if he has no diploma, he may be examined as to his qualifications to practise medicine and surgery.

This is the method of admitting candidates in Colorado, Illinois, Missouri, New Mexico, Rhode Island, Vermont, and Wisconsin.

IV. The applicant must hold a diploma issued by a proper medical college, which must be satisfactorily shown to belong to him.

This qualification is prescribed in California, Indiana,* Kansas, Kentucky, Michigan, Nebraska, Nevada, Ohio, Oklahoma Territory,† South Dakota, and Wyoming.

Indian Territory has a peculiar arrangement which in effect allows the Indians to follow their own customs in regard to doctors or medicine men of their own race, but in the Cherokee and Choctaw Nations provides for the examination of those not citizens of the nation who desire to settle therein to practise medicine. The law also requires the candidate to secure the indorsement of four or more citizens of the nation residing in the vicinity in which he desires to practise medicine.

There is no law protecting the residents of the Creek Nation from incompetent practitioners.

Additional Requirements.—In addition to the requirements classified under these four heads there are certain other requirements which are almost universally imposed—viz., that the candidate shall be twenty-one years of age, of good moral character, and have a good general education. In some States it is provided that he shall never have been convicted of a felony.‡

Removal to Another State.—There seems to be very little disposition manifested in the statute laws of the various States to facilitate the moving of a regularly licensed physician from one State to another. Several of the States make special arrangements for licensing regularly qualified physicians of sister States who change their residence and practice to those States, but in each case satisfactory evidence is required of the same or a similar degree of proficiency as that established to entitle other candidates to practise within the particular State.

Proving Diploma.—Whenever a candidate is admitted to practise medicine and surgery by virtue of a diploma, it is usually necessary for him to submit the diploma to some board appointed for the purpose of passing upon the qualifications of candidates, together with an affidavit that he is the lawful possessor of such diploma, that he has attended the full course of study

required for the degree, and that he is the person named in the diploma.

Issuing and Filing Certificate or License.—If upon examination of the papers submitted the board finds that the candidate has fulfilled the requirements of the law, they issue a certificate showing him to be entitled to practise medicine and surgery within that particular county or State. If the candidate is admitted upon examination, a like certificate is issued. In either case the law usually provides that this certificate shall be filed with some county officer in the county in which the physician resides and practises. The filing of this certificate with the county officer designated is an essential part of the requirements, and a physician is not entitled to practise and receive the benefits thereof until his certificate is so filed. The law generally provides that in case a physician removes to some county other than that in which he first filed his certificate he shall file a properly authenticated copy of the certificate in the county to which he removes; this copy will ordinarily be furnished by the officer with whom the certificate is originally filed upon the payment of a small fee.*

Enforcement of the Law.—In a very few States no penalty is prescribed for a violation of the law, but in nearly all States the law is enforced by fines, usually with an alternative penalty of imprisonment, and sometimes by fine and imprisonment conjunctively. The amount of the fine and the duration of the imprisonment is largely discretionary with the court, certain limits being prescribed for his direction, fixing the minimum and maximum amount of fine to be imposed and designating the longest and shortest periods of imprisonment to which the offender shall be committed. The smallest amount of fine fixed by any State is ten dollars, and the largest amount allowed to be imposed in any is five hundred dollars; the extreme periods of imprisonment vary from ten days to one year. In a few States, however, the payment of the fine is enforced by imprisonment until paid.

Recovery of Fee prohibited by Statute.—The statutes of several States expressly provide that any physician practising medicine unlawfully shall not be permitted to recover any fee or compensation for his services.† The right of the physician to recover for such services in States where there is no express prohibition of recovery has been the subject of judicial determination, and is fully treated in Chapter VI of this work.

Privileges to Non-resident Physicians. While every physician is, or at least ought to be, familiar with the statutes regulating the practice of medicine and surgery in his own State, it is also greatly to his interest to be informed upon the laws of the neighboring States, at least so far as they extend privileges to him as a legally qualified practitioner of a sister State.

Privilege of Attending Cases. The States of Connecticut, District of Columbia, Indiana, Kentucky, Maine, Massachusetts, Mississippi, New Hampshire, New Jersey, New York, Ohio, Pennsylvania, and Rhode Island accord to non-resident physicians and surgeons the privilege of practicing within each State, but they are not permitted in any case to maintain an office or have a place for meeting patients exclusively within such

* In Indiana, if the college issuing the diploma pretends to be not recognized as maintaining a sufficiently high standard of medical education, the applicant shall have the privilege of being examined as to his qualifications to practise medicine and surgery.

† In Oklahoma Territory, the candidate may be admitted upon examination if he has been actually engaged in the practice of medicine not less than five years.

‡ A felony may be generally defined as an offense that is punishable by capital punishment or by being imprisoned in the State prison.

* A physician of the State of California who practices in other counties without having his certificate filed in such other counties will be considered as practicing without license.

† Such provisions exist in Alabama, Georgia, Kentucky, Louisiana, Maryland, Michigan, Nebraska, North Carolina, Rhode Island, Virginia, and West Virginia.

States. In several of these States* the non-resident physicians' visits are restricted to "a particular case." The exact meaning of this restriction does not seem to have been judicially determined.

Before exercising the privilege in Mississippi the practitioner must procure a license from the State board of health, which license is granted to him without examination, and as a matter of right, upon his showing himself to be a legally qualified practitioner of another State. The privilege given by Indiana, New Hampshire, New York, Ohio, and Pennsylvania is restricted to physicians living "on the border of a neighboring State." The law of New Hampshire, however, permits non-resident physicians, irrespective of their place of residence, to attend their regular patients while sojourning in the State; it also allows landlords of summer hotels to employ physicians unlicensed in the State as hotel physicians to care for their guests or employees. New Jersey allows a physician of another State to take temporary charge of the practice of a physician of that State, a written request being first made to the State board of medical examiners.

Privilege of Consultation.—It is expressly provided that legally qualified physicians and surgeons from other States may meet in consultation with resident physicians in twenty-four States, to wit: Connecticut, Delaware, District of Columbia, Georgia, Idaho, Indiana, Louisiana, Maryland, Minnesota, Montana, Nebraska, New Hampshire, New Jersey, New York, North Carolina, North Dakota, Ohio, Pennsylvania, South Carolina, Tennessee, Utah, Virginia, West Virginia, and Wisconsin. The law of Georgia restricts such consultation to "a special case," and expressly provides that a non-resident physician shall not be permitted to engage in a continuous practice or consultation in connection with a resident physician or surgeon.

It will be observed that not all of the States which allow non-residents to attend patients within their borders expressly give them the right to meet resident physicians in consultation; but applying the general maxim of law, *Major continet in se minorem*, it may be stated generally that any non-resident physician having the right to enter a State to practise medicine has also the right to meet a resident physician there in consultation.

Proceedings of Societies.

SOCIETY OF THE ALUMNI OF THE CITY (CHARITY) HOSPITAL.

(Meeting of November 9, 1898.)

The President, Dr. WALTER B. JOHNSON, in the Chair.

Fracture of the Neck of the Femur.—Dr. FIELDING LEWIS TAYLOR presented the following case. (See page 86.)

Dr. RAMON GUITÉRAS asked how long after the accident did he see her.

Dr. TAYLOR said he saw her the next day. The shortening was not apparent for some days. This was

* In Kentucky, Maine, Massachusetts, and Rhode Island, the visit is restricted to a "particular case"; in Kentucky, to a "particular case or family"; in the District of Columbia, such physicians are permitted to attend "specified cases."

said to rather indicate fracture of the small part of the neck. After the bandages were taken off she had an attack of synovitis of the knee, probably due to the long-continued extension in a patient subject to rheumatic attacks.

Dr. GUITÉRAS asked the speaker to what he attributed the success of the cure in that case.

Dr. TAYLOR said principally to sustaining the woman's strength by massage, so as to enable her to stand the long confinement to bed, and also to the use of lateral sand bags, which tended to prevent false motion between the fragments.

Dr. GUITÉRAS asked how long he kept the buck on.

Dr. TAYLOR said he kept it on about a month; he did not care to move it earlier, as the patient seemed to be getting on comfortably. When the extension apparatus was removed the union was not yet firm.

A Perineal Cannula.—Dr. GUITÉRAS presented a perineal cannula. This instrument was about four inches and a half long, and pointed at the distal end; at the proximal end it had a handle on its lower aspect, and extending along the whole upper surface was a groove in which a knife could be run or passed. This perineal cannula was used in cases of tight stricture, where it was difficult to get into the bladder, and where nothing could be passed by the stricture. The method of doing this was by introducing the finger into the rectum and pressing its end against the apex of the prostate, then this cannula or trocar was run through the perineum, so that it could be felt passing by the end of the finger and entering into the prostatic urethra. The stylet was then removed and the urine escaped through the cannula, showing that the instrument was in the bladder, and by running a knife along the groove an incision could be made into that viscus. A grooved director could then be pushed in along the groove of the instrument, and the opening could be enlarged accordingly. The remainder of the operation in cases of stricture was performed in the usual manner. It simply took the place of the blind stabbing that one did with the knife in cases of retention of urine, and presented a certain guide for opening the bladder. Often in doing a perineal section it was difficult to strike the bladder, and finally, perhaps, one opened the prostatic urethra with the tip of the knife, the urine escaped, the bladder collapsed, and then it was almost impossible to enter the organ. He thought it was a very important thing to have a guide in finding the bladder, and it was not a good thing to enter around blindly in the perineum.

Dr. W. L. BAKER asked how the instrument differed from the one he had presented years ago.

Dr. GUITÉRAS said that the handle was placed on the stylet antero-posteriorly instead of laterally, and also that the former was not long enough. In fatty perineums there was quite a distance from the perineum to the bladder. It was sometimes necessary to insert the finger through the perineal wound for three inches before being able to enter the neck of the bladder.

Dr. BROOKS H. WELLS thought the instrument might be useful in other portions of the body than the perineum. It was practically a grooved director, and at the same time was a cannula allowing the escape of pus. It embodied an ingenious idea.

An Imbedded Pessary removed from a Vagina.—Dr. WELLS presented a specimen which was similar to one he had shown the society several years ago. It was an unusually large, old-fashioned, hard-rubber ring pessary, which had been removed from the vagina of a

woman six years after the menopause. She had suffered from a discharge which had led to the suspicion of cancer, but on examination the pessary had been found, having been put there at some previous time; she did not know when. Partly because of the incrustation of salts and partly from natural atrophy, the vagina had ulcerated and contracted around the ring of the pessary, so that it had almost been completely imbedded in the vaginal walls. These imbedded pessaries had been found quite often ten years ago, but nowadays they were quite a rarity.

(To be concluded.)

Book Notices.

System of Diseases of the Eye. By American, British, Dutch, French, German, and Spanish Authors. Edited by WILLIAM F. NORRIS, A. M., M. D., and CHARLES A. OLIVER, A. M., M. D., of Philadelphia. Volume III. Local Diseases, Glaucoma, Wounds and Injuries, Operations. With Fifty Full-page Plates and One Hundred and Eighty-six Text Illustrations. Philadelphia: J. B. Lippincott Company, 1898. Pp. xii-3 to 962.

THIS volume is probably the most practical of the *System*, inasmuch as it deals with the clinical aspect of the subject. There are fourteen papers in the volume, eight by American, three by British, and three by German authors, and they cover most of the ground of clinical ophthalmology, except diseases of the cornea and of the lens and anomalies of the ocular muscles. A review of all the subjects treated of in the volume is impossible within the limits allotted to the reviewer in the pages of a journal of general medicine.

The first article is by Dr. Bull, on Diseases of the Orbit. The subject is treated exhaustively, but is not illustrated. A large portion of the paper is devoted to the subject of orbital tumors, and Dr. Bull makes the emphatic statement that in the case of malignant, non-encapsulated tumors repeated operations undoubtedly shorten the life of the patient.

The second and third articles are by Dr. Harlan, on Diseases of the Eyelids, and The Operations performed on the Eyelids, and give a clear and detailed account of the whole subject. The exposition of the surgery of blepharoplasty is particularly satisfactory.

The fourth article, on Diseases of the Lacrymal Apparatus, is by Dr. Theobald, a recognized authority on the subject, and is well illustrated.

The fifth article, by Dr. Burnett, on Diseases of the Conjunctiva and Sclera, is of value inasmuch as it brings down to the present time what is known of the influence of micro-organisms in atiology. Among other interesting curiosities, he refers to the production of astigmatism by pterygium and the consequent necessity of an early operation for its removal.

The sixth article, on Diseases of the Iris and Ciliary Body, is by Bradley and Stephenson, and the seventh, on Diseases of the Choroid and Vitreous, is by Gräff. They are both well worth careful reading, especially what Dr. Gräff has to say on the differential diagnosis of choroidal tumors. He agrees with Fuchs that the stage at which the eye is enucleated has little to do with the occurrence of metastasis.

The eighth article, by Schnabel, on the Anatomy of Staphyloma Posticum and its Relationship to Myopia, is of great interest. He holds with Edward Jaeger that conus is a congenital anomaly and may exist, as we all know, in emmetropia and hypermetropia, as well as in myopia; and that it has no necessary connection with posterior sclerotic-chorioiditis, so called. Hence there is no danger of macular chorio-retinitis occurring in primarily emmetropic eyes which have subsequently acquired myopia.

The ninth article, on Diseases of the Retina, is by Schoelb, and is a long and exhaustive presentation of an important subject, especially in the matter of detachment of the retina.

The tenth article is on Diseases of the Optic Nerve, by Deyl, who does not consider Leber's theory as to the causation of choked disc sufficiently substantiated. One criticism that may be made on this paper is to call attention to the insufficient space given to atrophy of the optic nerve.

The eleventh article, on Glaucoma, is by Priestley Smith. As is well known, he advises iridectomy in simple chronic glaucoma, with the addition of a scleral puncture, and believes in operating as long as there is any vision left. He admits, however, that the result is in the majority of cases problematical, and that any improvement in the vision is almost hopeless. He considers also that but little can be expected from medicinal measures.

The twelfth article is by Dr. Grüening, on Wounds and Injuries of the Eyeball, a wide subject, but well handled in the comparatively brief space allotted to it. The same may be said of the next paper, on Sympathetic Ophthalmia, by Dr. Randolph.

The fourteenth and final article of the volume is by Dr. Knapp, on the Operations Usually Performed in Ophthalmic Surgery. A large portion of this article is devoted to the subject of cataract and the operations for its relief, and the author's remarks are eminently wise and judicious. The remarks on tenotomy for the relief of muscular asthenopia are brief but just.

It is to be hoped that the long delay in the appearance of this volume will not occur in the appearance of the fourth and concluding volume of the *System*.

Mittheilungen aus der Augenklinik des carolinischen medico-chirurgischen Instituts zu Stockholm. Herausgegeben von Dr. J. WIDMARK, Professor der Augenheilkunde am carolinischen medico-chirurgischen Institut zu Stockholm. Erstes Heft. Mit einer Tafel und vier Abbildungen im Text. Jena: Gustav Fischer, 1898. Pp. 251. [Preis, 7 Marks.]

THIS brochure consists of a series of six articles, four of them by Dr. Widmark, all previously published in various Scandinavian journals.

The first article is entitled The Position of the Pupillo-muscular Bundles of Nerve Fibres in the Optic Tract, by Dr. Widmark, and the cases to which he alludes are based upon one case. He believes that by his observations on this case he is able to explain the different results obtained by A. J. L. F. and Bunge. At the same time, as to the question, in his case, the bundle of nerve fibres was not, as described by Bunge and Fuchs, which he says, that the bundle of fibres occupied the posterior part of the optic tract, he thinks that the difference may be explained by the fact that

Vossius examined the tract higher up than Uthoff and Bunge. He confirms the observations of Bunge and Henschen that the bundle between the chiasm and the cerebral peduncle occupies a central position in the tract.

The second paper is also by Widmark, and consists of statistical observations on myopia among school children and students, which seem to bear out the statement that the increase of myopia is more marked in girls than in boys.

The third paper is by Widmark, on The Limit of the Visible Spectrum from the Violet End, and he draws the following conclusions: 1. The normal human eye can perceive only a small portion of the ultra-violet rays. The limit of the visible spectrum varies in different individuals, but lies within the limits of L-M, and only exceptionally outside of these lines. 2. The rays are directly perceptible, and not by fluorescence. 3. They are perceived more readily eccentrically than centrally. 4. Elderly persons perceive a smaller portion of the ultra-violet rays than younger persons. This difference is but little noticeable up to the fifty-fifth year, but after the sixty-fourth year it becomes marked. The limit of the visible spectrum after this period usually lies within the violet field. 5. The reason for this slight power of the human eye to recognize the ultra-violet rays lies mainly in the absorption through the lens, and if the lens is removed a much greater portion of these rays will be perceived, as is frequently observed in patients operated on for cataract.

The fourth paper is by Dalén, on Experimental Observations on the Disinfection of the Conjunctival Sac, and will prove of great interest to the surgeon and bacteriologist.

The fifth paper, The Mechanical and Therapeutical Treatment of Trachoma, is by Hellgren. In it are presented at considerable length the various surgical procedures now employed in the treatment of this disease.

The sixth and final paper is by Widmark, on The Operative Treatment of Immature and Partial Stationary Cataracts. This is a long and carefully considered statement of a subject of great interest to the ophthalmic surgeon, based on observations by the author and other writers, and will well repay perusal.

Ophthalmic Diseases and Therapeutics. By A. B. NORTON, M. D., Professor of Ophthalmology in the College of the New York Ophthalmic Hospital, etc. With Ninety Illustrations and Eighteen Chromolithographic Figures. Second edition, revised and enlarged. Philadelphia: Boericke & Tafel, 1898. Pp. xiii-17 to 647.

THIS is a volume in which 138 pages are devoted to an account of the drugs employed by the author in ophthalmic practice.

The first four chapters, covering 82 pages, deal with the methods employed in examining the eye, with the use of the ophthalmoscope, with the great subject of refraction and accommodation, and with dioptry. Then follow chapters on the various diseases of the eye, including the affections of the muscles. The author's pathology is at times faulty, and far too much importance is laid upon the administration of drugs, and far too little attention is given to surgical treatment, either for the relief of deformities or for the cure of diseased conditions. In the chapter on diseases of the laryngeal apparatus no mention is made of Theobald's probes for the cure of stricture of the duct.

The author states that empyema of the frontal sinus is extremely rare, but this is not the experience of the modern ophthalmologist.

Very little space is given to the consideration of the modern ideas of strabismus, and simple tenotomy of one or both internal recti muscles will fail to effect a cure in the majority of cases. The author protests most emphatically against the prevalent operation of graduated tenotomies for the relief of heterophoria, and in this he seems to be in accord with many of the best observers.

The author has a modified belief in the efficacy of the treatment of cataract by the administration of drugs according to the homeopathic law. "But after degeneration of the lens fibres has taken place, no remedy will be found of avail in restoring the lost transparency of the lens."

The colored lithographs are good, but some of the black-and-white illustrations are poorly done. There is a fairly good index and there is a brief bibliography. The book is well printed on good paper.

A Text-book of Physiological Chemistry. By OLOF HAMMARSTEN, Professor of Medical and Physiological Chemistry in the University of Upsala. Authorized Translation from the Author's Enlarged and Revised Third German Edition by JOHN A. MANDEL, Professor of Inorganic Chemistry and Physics, and Adjunct Professor of Physiological Chemistry in the University and Bellevue Hospital Medical College. Second Edition. First Thousand. New York: John Wiley & Sons. London: Chapman & Hill, 1898. Pp. x-705.

THE changes in the second American edition of this admirable work, as compared with the first, are few. The foods have been more amply considered, as was necessary, and the revision throughout has been that which advances in the study of physiological chemistry have required. One innovation in this edition is the inclusion of a reference bibliography, the importance of which is self-evident. The work is exhaustive and authoritative, and can not but meet with appreciation. It is not one which may be read for pleasure, and in this respect perhaps it suffers by comparison with such a book as Bunge's work upon the same subject, but, on the other hand, it will be consulted and referred to with the comforting knowledge that no work is its superior in the field of which it treats.

A Treatise on Diseases of the Ear, together with a Brief Sketch of the Anatomy and Physiology of this Organ. By ALBERT H. BUCK, M. D., Clinical Professor of the Diseases of the Ear, College of Physicians and Surgeons, New York, etc. Third Revised Edition. New York: William Wood and Company, 1898. Pp. xii-592. [Price, \$3.50.]

So many works of this kind have recently appeared that it is difficult to present within the columns of a weekly journal a critical review which tells in a brief compass in just what particulars one manual differs from another. Suffice it to say that the one now under discussion is the presentation of long years of clinical experience by one who has had unusually good opportunities for observation and has improved them to the utmost. Three editions tell more than mere words can. The author is an "expansionist" in regard to the limits of otology, which have in recent years, he declares, been

enlarged by the annexation of the larger part of the domain of rhinology, and more lately by that of a localized portion of brain surgery, reference being made to the otitic origin of many intracranial diseases.

The present edition takes full note of this advance. The chapter on affections of the nasal cavities and the vault of the pharynx is written by Dr. Robert Lewis, and is unusually clear and lucid. Print and paper are excellent, and the book as a whole presents an attractive appearance.

We are inclined to believe that some of the rhinologists will be apt to take exception to the statement that otology has absorbed a large part of their domain. So far as practice here in New York is concerned, many rhinologists have taken up ear work and prosecuted it with success. However, argument on this point is not necessary.

One feature of the present volume which we would heartily commend is the author's judicious use of the clinical material which has come under his own notice. This is employed in the shape of brief histories, etc., which well illustrate the writer's various propositions.

Clinical Lectures on Mental Diseases. By T. S. CLouston, M. D. Edin., F. R. C. P. E., Physician Superintendent of the Royal Edinburgh Asylum for the Insane, etc. Fifth Edition. Philadelphia: Lea Brothers & Co., 1898. Pp. xii+727. [Price, \$4.25.]

THESE lectures are so well known and so highly esteemed that the appearance of a fifth edition of the work is as much a matter of course as that of the sixth, seventh, and doubtless many more will be. As is well known, the work is a very admirable one, erring, if at all, in being too conservative. This, however, is a fault in the right direction, and one is not likely to go amiss in following the teachings of Dr. Clouston. So far as alterations in the book are concerned, but few are apparent in the fifth edition; the most noticeable are a few fairly well executed illustrations.

Nursing: its Principles and Practice. For Hospital and Private Use. By ISABEL ADAMS HAMPTON, Late Superintendent of Nurses and Principal of the Training School for Nurses, Johns Hopkins Hospital, Baltimore, etc. Revised and enlarged. Illustrated. Philadelphia: W. B. Saunders, 1898. Pp. 6 to 512.

WE heartily commend this very excellent text-book to those concerned in the education and training of nurses. Its character has been described before. Of the second edition it is sufficient to say that it does not differ materially from the first.

Material Medica, Pharmacy, Pharmacology, and Therapeutics. By W. HALE WHITE, M. D., F. R. C. P., Physician to and Lecturer on Pharmacology and Therapeutics at Guy's Hospital, London, etc. Edited by REYNOLD W. WILSON, M. A., M. D., LL. D., Professor of Medicine and Therapeutics at the New York Post-graduate Medical School, etc. Fourth American Edition, thoroughly revised. Philadelphia: P. Blakiston's Son & Co., 1898. Pp. 8 to 704. [Price, \$3.]

THE well-deserved success this book has had is not likely to suffer diminution from any fault of the fourth American edition. Such revision as pharmacological

progress has demanded has been conscientiously done, and the work is an admirable and useful presentation of a none too easy subject. For these reasons the popularity of the book with teachers is not to be wondered at.

1. *Handbook of Hygiene and Sanitary Science.* By GEORGE WILSON, M. A., M. D., LL. D. Edin., F. R. S. Edin., D. P. H. Camb., Fellow of the Sanitary Institute of Great Britain, etc. Eighth Edition. London: J. & A. Churchill, Philadelphia: P. Blakiston's Son & Co., 1898. Pp. xxvii+798. [Price, \$3.]

WHEN a work such as this has reached an eighth edition the task of the reviewer can be but perfunctory. That the book has always kept pace with the developments of sanitary science is well known, and the latest edition is renewed evidence of the zeal and conscientiousness of the author. To those familiar with the book in its earlier editions it will appear that a considerable revision has been done, few of the chapters having escaped, and it will also appear that the book represents all that is newest and best in sanitary knowledge. It is true that much of the author's expressed skepticism upon serum treatment and immunization will not meet with general concurrence, but, while he is bacteriologically somewhat of a pessimist, he can not be accused of insincerity or of having arrived at his discouraging conclusions without mature reflection upon evidence which to him has been sufficiently convincing.

BOOKS, ETC., RECEIVED.

The Practice of Obstetrics. By American Authors. Edited by Charles Jewett, M. D., Professor of Obstetrics and Diseases of Children in the Long Island College Hospital. Illustrated with Four Hundred and Forty-one Engravings, Thirty-four of which are in Colors, and Twenty-two Colored Plates. New York and Philadelphia: Lea Brothers & Co., 1899. Pp. xiii+1; to 768. [Price, \$5.]

A Manual of Bacteriology. By Herbert C. Williams, M. D., Professor of Pathology and Bacteriology, Medical Department, University of Buffalo. With Seventy-eight Illustrations. Philadelphia: P. Blakiston's Son & Co., 1899. Pp. x + 10 to 263. [Price, \$1.50.]

Puerto Rico and its Resources. By Frederick A. Ober, Author of *Camps in the Caribbees*, *Travels in Mexico*, etc. With Maps and Illustrations. New York: D. Appleton and Company, 1899. Pp. xiii + 282. [Price, \$1.50.]

Organothérapie ou opothérapie. Par le Dr. C. Hillemand, Ancien interne des hôpitaux de Paris, etc. Paris: G. Steinheil, 1899. [Prix, 0 fr. 75.]

Formulaire des médicaments nouveaux pour 1899. Par H. Boespillon-Lamouin, Membre des sociétés de pharmacie et de thérapeutique, etc. Avec une introduction par Henri Huchard, Membre de l'Académie de médecine. Paris: J. B. Baillière et C^s, 1899. Pp. viii+9 to 332.

Illinois State Board of Health. Appendix to the
Twentieth Annual Report, 1897.

The Sixth Annual Report of the Maryland Asylum,
Baltimore, 1893

Diseases of the Ear as a Specialty. By F. M. Anderson, M. D., of Detroit. [Report of the Otorhinolaryngological Surgeon.]

Assigned Dates: 1994-1995, 1996, 1997, and 1998
 Recognition: By J. A. C. G. (1994), M. D. (1995), and
 from the *Hebrew Bible* (1996)

Diseases of the Alimentary Canal.—Treatment. By James Osborne De Courcy, M. D. Read before the St. Clair County, Illinois, Medical Society, June 7, 1894.

Sanitarium Treatment of Pulmonary Tuberculosis. By J. Edward Stubbert, M. D., and Stephen W. Wells, M. D., of Liberty, N. Y. [Reprinted from the *St. Louis Medical Gazette*.]

New Inventions, etc.

A NEW OPHTHALMOSCOPE.

By GEORGE M. GOULD, M. D.,
PHILADELPHIA.

THE illustrations herewith given of a new ophthalmoscope are of the same size as the instrument, and present views of the anterior and posterior surfaces. In the following points the device seems superior to others.

1. The absence of the Rekoss disc. The lenses are arranged in two series, those most used at one end, and the higher numbers, both plus and minus, at the other. The arrangement may be changed so that a surgeon with high ametropia, except in rare instances, will still seldom be compelled to transfer the mirror so as to use the high-power lenses. The transfer, however, requires but an instant.

2. There are sixty lenses, all the lower powers proceeding from zero by 0.5 D. intervals; the highest minus lens being 10 D., the highest plus, 30 D.

3. The absence of a handle, the instrument itself, when used, being grasped by the hand.

4. The mirror is turned at any angle so that examination of an eye is easy whatever the position of the patient's head.

5. The light hole is protected from side light, thus increasing the perfection of the illumination.

6. The side light hole, by an ingenious device, can at pleasure be made large or small.

7. No case is required, the instrument, though light, being so strong and durable that it may be slipped into the pocket, or with other things into the hand bag.

8. Correspondence concerning the ophthalmoscope should be addressed to the manufacturers, Messrs. Wall & Ochs, 1716 Chestnut Street, Philadelphia.

Miscellany.

The Nutritive Value of Sugar.—The *Lyon médical* for December 18th, quoting *Médecine moderne* for October 3d, says that there has recently been made in the German army during the manoeuvres a series of interesting experiments upon the nutritive and tonic properties of sugar.

Ten men were chosen from each company from among the least vigorous as subjects of experiment, and ten others were used as checks. The former received at first ten lumps of sugar daily; then the daily ration was progressively raised to ten and twelve lumps. The results were as follows: During the manoeuvres the weight of the men dieted with sugar increased in a greater proportion than that of the others. They were at the same time in better health and more vigorous than prior to the experiments. On a march a lump of sugar appeased both hunger and thirst. Fatigue and insolation were easily combated by the aid of this article.

In consequence of these experiments, M. Leitenstorfer, under whose direction they were made, proposes to introduce sugar into the military dietary in three different ways: 1. As a supplementary article to improve the daily ration of the soldier. 2. As an integral part of the reserve supplies and provisions of strongholds, hospitals, and ships. 3. As a temporary ration to strengthen the soldiers and to sustain their vigor while on the march.

The *Revue scientifique*, which gives a résumé of the experiments made by M. Leitenstorfer, adds that sugar appears to be indicated to replace alcohol or wine under the various conditions when it is commonly considered desirable to include the latter in rations. Sugar, it says, affords, in short, the same stimulation as alcohol, but without any danger. It has, moreover, the incontestable advantage of being a muscular aliment of the first rank, combating and at the same time preventing fatigue.

Glycosuria cured in Twenty-eight Days.—Dr. Michaux (*Doximétrie*, October; *Lyon médical*, December 18th) reports the case of a man of fifty-eight who in eight months had lost fourteen pounds in weight following upon digestive troubles. Analysis of his urine disclosed six hundred grains of sugar to the quart. No indication was given of the quantity of urine passed in twenty-four hours.

The regimen was left unchanged, but the patient was given (daily?) four granules, containing each one hundred and twentieth of a grain of arsenate of strychnine, a sixtieth of a grain of arsenate of iron, a third of a grain of benzoate of lithia, and a sixtieth of a grain of quassine. This treatment was continued without interruption from August 24th to September 24th. All the functional troubles have disappeared, and there is no trace of sugar from the urine.

The Infection of Man with the Hoof-and-Mouth Disease.—According to the *Pharmaceutical Journal* for June 1st, quoted by the *Journal of Comparative Medicine and Veterinary Archives* for December, an attack of

the slaughterhouse in Dresden was infected in the following manner with hoof-and-mouth disease, while caring for an infected herd: He was smoking at his work and touched his cigar with his dirty hands. He was afterward seized with a violent fever, and blisters appeared in his mouth and on his toes. The man was unable to work for a week. In the neighborhood of Zabern, moreover, two milkmaids were similarly afflicted after they had drunk from a milk bucket the milk of cows which had not yet fully recovered from the aphtha contagion.

A Distinction with a Difference.—The *Sanitary Inspector* for December says that a comical little anti-vaccination paper states that "disease germs only thrive where disease exists"; nevertheless, various trustworthy observers have found the bacillus of diphtheria in the throats of children in good health of whom some developed diphtheria a few days later after the germs had had time to thrive and proliferate enough of their specific toxin to poison the system. Those who would teach the truth should say: "Infectious diseases exist only where disease germs thrive."

Odor as a Symptom of Disease.—Dr. J. H. McCassey (*Medical Age*, December 27th) says that diseases have their characteristic odors. Persons who have visited many insane asylums recognize the same familiar odor of the insane. General paresis of the insane affords us a typical example. It is a true cerebral disease, physiologically, pathologically, and psychologically. In it the substances of the convolutions of the brain undergo a process of degeneration or atrophy, which finally invades the whole nervous system. The nerve and mind tissue die slowly and progressively. The blood current carries the waste tissue to the lungs for aeration, and the result is the foul, characteristic odor of this disease.

It is not insane asylums alone, but prisons, jails, workhouses, armies in camp, churches, schools, and nearly every household, that have their characteristic odors. It is when the insane, the prisoners, and the soldiers are aggregated in large groups or battalions that their characteristic odor is recognized by our much-neglected "sneller."

As said before, many diseases have characteristic odors, and by the exercise of the sense of smell they could be utilized in differential diagnosis. For example, favus has a mousey odor; rheumatism has a copious, sour-smelling, acid sweat. A person afflicted with pyæmia has a sweet, nauseating breath. The rank, unbearable odor of pus from the middle ear tells the tale of the decay of osseous tissue. In scurvy the odor is putrid; in chronic peritonitis, musky; in syphilis, sweet; in scrofula, like stale beer; in intermittent fever, like fresh-baked brown bread; in fevers, ammoniacal; in hysteria, like violets or pineapples. Measles, diphtheria, typhoid fever, epilepsy, phthisis, etc., have characteristic odors.

A Mummified Fetus expelled Three Days after Accouchement.—M. Bendaan and M. Bendaan (*Indépendance médicale*, December 21st) have recently to the Obstetrical Society of Paris (of which) a primipara expelled during a violent contraction a mummified fetus three days after a normal delivery. Rad ceraphy showed that the mummified fetus was in a contracted form, which accords with the fact that it was expelled three days after a normal delivery. The mummified fetus was ten months in the uterus. The mother was healthy and the mummified fetus was expelled after three days.

other, notwithstanding, continued to develop to term. Examination of the placenta showed nothing abnormal.

The Alcohol Question and Hospital Physicians.—M. Legendre (*Indépendance médicale*, December 21st), in a communication to the *Société médicale des hôpitaux*, thinks that hospital physicians can exercise great influence in the struggle against alcoholism. He has had printed a brochure setting forth all the evil effects of the abuse of alcohol and of the alcoholic mania, a copy of which brochure is given to every patient on his entry into the hospital.

Endermol.—This new remedy, according to the *Druggists' Circular and Chemical Gazette* for December, is nicotine salicylate. It crystallizes in tablets, melting at 117.5°, and is free from water. It contains seventy-five per cent. of the alkaloid.

Orthoform in the Treatment of Fissures of the Nipple.—L. Toiséire (*Thèse de Paris*, 1898; *Presse médicale*, December 21th) regards orthoform as an excellent local anæsthetic and to some extent an antiseptic. It may be applied to fissures of the nipple by insufflation or spread in a thin layer on a compress. Before each nursing, it is to be washed off with a boric-acid solution. He has observed excellent results from its employment.

Pneumatic Gymnastics; a New Method of Treatment of Gastric Myasthenia.—This was the title of a very interesting paper read by Dr. Fenton B. Turck, of Chicago, before the Section of Pharmacology and Therapeutics at the sixty-sixth annual meeting of the British Medical Association in Edinburgh, July, 1898. An abstract of it was published in the *British Medical Journal* for October 29th, the substance of which, amplified from the author's manuscript, is as follows: Notwithstanding some recent surgical achievements that might be interpreted as indicating the contrary, Dr. Turck thought the stomach was still to be considered as one of the most important of all the viscera. Its function, however, was largely a mechanical one; it was a temporary receptacle for the ingested food; in it, together with a certain amount of chemical digestion, the latter was subjected to the churning and mincing process that prepared it for its further treatment and absorption in the intestine. It was this motor function of the stomach that gave it its chief importance, and when it was deranged there was a condition of gastric weakness, or myasthenia, and there were commonly, as attendants or results, extensive disturbances of other organs, and, in short, the whole complex phenomena of dyspepsia and its concomitant disorders. The treatment of this gastric myasthenia had so far been more palliative than directly curative; the distressing symptoms had been relieved so far as possible, and the organ put into a condition more to allow Nature to do her work of restoration than to assist actively in the process. When matters were not so bad that this *vis medicatrix Nature* was not seriously embarrassed or even altogether obstructed, Dr. Turck said, this plan was effective in the course of a period of time, long enough at the very least, and often altogether too long, for the comfort, economy, and even the best welfare of the patient.

Dr. Turck placed these methods of treatment in the following order:

1. Diet, which might be palliative, but was not in itself a curative measure. As affording Nature a chance, as well as relieving one of the more distressing symp-

toms, it might be relatively efficient, but it did not meet the requirements of an actual remedy.

2. Lavage. This was often palliative and might even have a slight curative action in mild cases, but in many others it only increased the muscular asthenia and led to more rapid emaciation.

3. Baths.

4. General gymnastics could not directly act on the stomach, and their effectiveness was only in their general action on the system. They were, therefore, only auxiliaries of uncertain value, aids to Nature, it might be, in her efforts to throw off disease, but requiring careful oversight and good judgment in their management in any particular case. They were not essentially, but only incidentally or accidentally, remedial, and might be even damaging under certain conditions.

5. Electricity had been very strongly advocated in quite recent publications as a remedy for gastric dilatation and myasthenia, and would appear at first sight to be a rational one. One of its disadvantages was the difficulty of its uniform and equable application. The electrode, whether applied externally or internally, could only direct the current in a haphazard manner as regarded the musculature, and, besides this, there was, as the result of careful experimentation, a serious doubt as to the efficacy of the current in provoking muscular contractions through the gastric mucosa at all. Taking both these facts together, the difficulty of systematic electrization, and the serious doubt as to the real efficacy of this method, it was left in a rather unsatisfactory position, and could not in any event be admitted as completely meeting the indications of a satisfactory treatment. In any event the cases reported by its advocates should have a more careful analysis than had yet been given them before their claims could be fully admitted. The mere statement of the disappearance of symptoms for an unstated period was not adequate evidence for the decision of a question such as the effectiveness of this or that remedial method or agency.

6. Drugs. These were the common resource, and were used often without any discrimination or even any recognition of the real state of affairs. While they could be rationally used sometimes for the palliation of distressing symptoms, the fact probably was that in the aggregate they did as much harm as good. There might also be a certain amount of reasonableness in giving tonics for the muscular weakness, but the remedial action must be slight at least.

7. Surgical measures, such as Bercher's operation, were, of course, only a last resort, and the most they could effect was the mechanical relief of the dilatation, not the cure of the myasthenia. They could, therefore, be left unconsidered.

Since all the hitherto available methods seemed to have their drawbacks, Dr. Turck said that he had endeavored to find one that would be at least rational in its conception, and could be practically applied without danger or serious inconvenience to the subject. General abdominal gymnastic exercises, while they might be of use, he thought, could not be directly localized on the gastric muscle, which was the part desired to be affected directly. The internal situation of the organ and the extent of its muscular walls were such that it could be uniformly exercised by one method only—that of expansion and contraction. Dr. Turck stated that he had devised for this purpose a method which he called pneumatic gymnastics, which consisted in alternating distention and contraction of the stomach by means of

regulated air pressure, which might, if desirable, be combined with other therapeutic measures, such as the introduction of hot or cold air or vapors suited for gastric treatment. The apparatus, he said, was simple, and consisted of two parallel attached rubber tubes of unequal calibre. The smaller and shorter tube, when introduced, reached just through the cardiac orifice, while the larger and longer reached the greater curvature. The air tank, or bulb, was attached to one tube, and to the other a manometer for regulating the pressure; either tube might be used as the inlet, he said, according to the conditions of the gastric muscle, but in most cases it was found more convenient and perfectly safe to use the larger tube for this purpose and to use the smaller one only in cases of very profound myasthenia, when a very free outlet was advisable. The double tube was, if anything, more readily introduced than the ordinary stomach tube, its flattened shape favoring its passage, and, while flexible, it was not so readily collapsed as a single tube of equal thickness of wall would be.

Dr. Turek further stated that he had devised a method of using dry and moist heat (vapor) in connection with pneumatic gymnastics of the stomach. The forced air, he said, passed through a heated coil controlled by a thermometer, and was allowed to pass into the stomach through a special tube. By this method the entire stomach was affected by the thermal agent, instead of only a portion, as in lavage. The moist air, on the other hand, was produced by passing the air through a rubber tube which was long enough to form a ring at the bottom of a bottle holding from three to four quarts. The end of the rubber tube inside of the bottle was closed and the air was, instead, forced out through a number of small openings made along that part of the tube which touched the bottom of the bottle. The bottle was two thirds filled with water having a temperature of about 10° C. above the temperature desired for the moist air. By this means the air rushing through the water was thoroughly saturated with water vapor, and was, at the same time, perfectly and uniformly heated. Dr. Turek said that experiments had shown that the air would pass out of the farther end of the stomach tube at a temperature approximately 10° C. below the temperature of the water in the bottle, and the temperature of the air passed into the stomach was, therefore, very perfectly regulated by simply regulating the temperature of the water in the bottle. The dry and moist heat were of great and therapeutic value, he said, used in this way under full control of the operator.

In certain cases, Dr. Turek said, in which the cardiac orifice of the esophagus did not close together around the tube, or when the pylorus remained patent, it was necessary to use a modification of the apparatus, which consisted in a light, readily inflatable rubber bag opening into both tubes, which would confine the air that would otherwise escape around the tube or pass into the intestines. Another use for the bag was in cases where it might be desirable to protect the walls of the stomach from the air introduced, which might, under certain conditions, act as an irritant, and might thus be employed at varying temperatures without fear of injury. The distended rubber bag molded itself to the shape of the stomach, and the amount of pressure was revealed by the manometer. It was perfectly under the control of the operator. When it was relieved the air was rapidly forced out by the elasticity and contractility of the stomach walls, aided by the pressure of

the gastric and abdominal muscles. In this way, Dr. Turek said, there could be produced an alternating expansion and contraction of the muscular walls, a sort of gastric passive exercise or massage that, when properly administered, had the same effect upon the muscular coats as similar manipulations did on the external muscles of the body, in so far as stimulating function and nutrition was concerned. Under ordinary conditions both the pyloric and cardiac orifices contracted as soon as moderate pressure was applied, and were relaxed as it was withdrawn, and the open outlet tube gave the air free exit. The mechanism was, therefore, he said, practically the same as that of the normal contraction and dilatation of the stomach, and this formed a natural mechanical aid in the treatment of gastric myasthenia and atony.

The action of the method of pneumatic gymnastics was, however, not limited to its simple mechanical exercising of the gastric muscle. Both local and general effects on circulation and secretion were produced, and these must have a direct or indirect influence on the nutrition and functions of the organ. While chronic atony and distention of the stomach walls could have no possible beneficial effect, alternating, or temporary, stretching of the stomach, as of other organs, acted as an excitant to the circulation. According to Bensley, said Dr. Turek, distention seemed to favor circulation, because the blood-vessels were more easily injected in a moderately distended stomach than in an empty one. The rich venous plexus of veins within the submucosa was sufficiently large to hold a considerable quantity of blood. This, he thought, must be the case when the valves within the veins coming from the stomach were temporarily closed. When the valves were closed a contraction of the circular muscle was sufficient to drive all the blood from the underlying veins. It was, therefore, possible that a rhythmic contraction of any part of the stomach might force the circulation through its walls. The arrangement of the lymphatics was much the same as that of the veins, and the consideration above mentioned applied equally well to them. Dr. Turek thought that when we considered the resistance to be overcome while the lymph passed through so many networks before the receptaculum chyli was reached, it made it plausible to state that the circulation was favored by muscular contraction.

It would be readily seen, he said, how the alternating dilatation and contraction of the gastric walls might favor local circulation. The action might be slight at first, but each application increased the nutrition of the parts and, consequently, the vigor and force of the muscular tissues. The secretion of the gastric glands must also be at least incidentally affected, if not stimulated, with the better and more regulated blood supply, thus also favoring a restoration of the atonic organ to its normal state.

The action of this method on the circulation was not altogether local, as was easily shown by the following considerations: The splanchnic area was the largest blood reservoir in the body, and sudden disturbances in the afflux or efflux of blood to or from it had most decided effects on the regulating mechanism of the heart and the circulation of the blood. This was shown by the well known phenomenon of syncope, and even the sudden emptying of a distended bladder or sudden withdrawal of ascitic fluid had been known to produce it, by the derangement of the abdominal blood supply thus induced. After section of the splanchnic nerves, in the

rabbit, the placing of the animal upon its feet might cause instant death from the afflux of blood to the abdominal organs and consequent cerebral anemia. A chronically dilated stomach, with consequent passive venous hyperemia from obstructive stasis, was a very seriously disturbing factor in the organism, and whatever could relieve it acted not only locally upon the organ itself, but on the system generally, and relieved a vast number of, perhaps, only vaguely felt but very real and important symptoms.

Dr. Turck summarized the action of pneumatic gymnastics as follows:

1. Distention (partial) of the stomach with air stretched its walls, and this was opposed by the gastric muscles themselves, those of the abdomen and the diaphragm, and by the intra-abdominal pressure.

2. The succeeding contraction was produced through the muscular apparatus noted above, and by the intra-abdominal pressure.

3. The expansion and retraction of the gastric walls acted as a stimulant and exercise to the gastric musculature and circulation (1) by causing venous outflow and filling of veins from the capillaries; (2) by the mechanical muscular contraction acting as an arterial stimulant. Secretion was also directly and incidentally modified in a normal direction.

4. Distention of the stomach with air increased the pressure within the whole abdominal cavity, causing a pressure that forced the blood out of the veins and through the portal circulation. Increase of work was thus thrown upon the heart, calling for more vigorous systolic impulse. More blood was thus forced into the portal circulation, and more blood passed through the right heart.

5. Contraction of the stomach by its own muscles and those of the diaphragm forced out the air and relieved intra-abdominal pressure. This caused the blood to flow rapidly into the splanchnic area, increasing the capillary flow. It might do this also by causing a slight negative pressure in the abdominal cavity.

6. The principle of alternately increasing and decreasing the intra-abdominal pressure by regulated gastric pneumo-gymnastics in the manner described tended also to act as an exercise for the vascular system, and to increase the tone of the splanchnic circulation.

Dr. Turck gave a detailed description of a number of experiments upon dogs in which he had demonstrated the gastric circulatory changes described in the foregoing as the effect of pneumatic gymnastics of the stomach. In every case, he said, the bluish venous congestion that preexisted had been changed to a bright arterial one by the operation, and the general circulatory and respiratory disturbances had often been suppressed and replaced by more normal conditions.

The therapeutic action of pneumatic massage was, first, to improve the motor power of the gastric musculature, as was shown by the improved condition of the gastric contents when examined, and also by the lessened time occupied by gastric digestion. It had, also, for a second effect a marked though seldom complete retraction of the dilatation, reducing the diameter of the stomach as much as four inches in some cases. Thirdly, there was with the increased power a compensatory hypertrophy of the gastric walls.

Dr. Turck further stated that a very important feature of value in this method was the general improvement in the circulation and nutrition of the patient which followed the use of pneumatic gymnastics. With

the rapid disappearance of the uncomfortable symptoms there was a marked gain in weight, in some cases amounting to ten or twelve pounds in a month.

The Atlanta Society of Medicine.—We learn from the *Atlanta Medical and Surgical Journal* for January that officers for the year 1899 have been elected as follows: President, Dr. W. S. Goldsmith; vice-president, Dr. Katherine Collins; secretary, Dr. Claude A. Smith; treasurer, Dr. E. Van Goidtsnoven; librarian, Dr. Mike Hohe.

The Medical Society of the State of New York.—The ninety-third annual meeting will be held in Albany on Tuesday, January 31st, and Wednesday and Thursday, February 1st and 2d, under the presidency of Dr. John O. Roe, of Rochester. The preliminary programme contains the following titles: The president's inaugural address, by Dr. John O. Roe; Fracture of the Cervical Vertebra, with Specimen, by Dr. Chauncey P. Biggs, of Ithaca; An Unusual Injury to the Kidney, with Specimen, by Dr. William D. Garlock, of Little Falls; Formaldehyde Disinfection, by Dr. William H. Park, of New York; The Close Relation between the Nasal and the Cranial Cavities, and between Nasal and Cranial Disease, by Dr. William C. Krauss, of Buffalo; The Importance of Early Examination and Treatment of Catarrhal Mouth Breathing in the Public Schools, by Dr. Clarence C. Rice; Some Practical Points in the Diagnosis of the more Common Forms of Nasal Obstruction, by Dr. Charles N. Cox, of Brooklyn; Intestinal Resection: Personal Experience, by Dr. William L. Cuddelback, of Port Jervis; The Dangers of the Long Tube Nursing Bottle, by Dr. Ernest Wende, of Buffalo; The Detection of Tuberculous Infection in Second-hand Clothing, by Dr. William G. Bissell, of Buffalo; The Improvement in General Anaesthesia on the Basis of Schleich's Principle of adapting the Boiling Point of the Narcotic to the Temperature of the Body, with Special Reference to Anesthol, by Dr. Willy Meyer, of New York; How to Treat Shock, by Dr. Robert H. M. Dabarn, of New York; Fever in Aseptic Surgery, by Dr. B. Farquhar Curtis, of New York; The Use of Streptococcus Antitoxine in Phlegmonous Inflammations, with a Report of a Case, by Algernon T. Bristow, of Brooklyn; Puerperal Insanity: A Cursory View for the General Practitioner, by Dr. Carlos F. Macdonald, of Pleasantville; Hygienic Camps, by Dr. Henry R. Hopkins, of Buffalo; Typhoid Fever in the Seventh Army Corps, by Dr. Henry P. De Forest, of Brooklyn; The Character and Treatment of the Gunshot Wounds in the Recent War, with a Report of Cases, by Dr. Henry B. Delafour, of Brooklyn; Cardiac Deficiency as Observed in the Soldiers of the Late War, by Dr. Henry W. Fairbairn, of Brooklyn; The Relations of Preventive Medicine to Political Economy, by Dr. George W. Brush, of Brooklyn; The Relation of the Consumptive to the State, by Dr. John H. Pryor, of Buffalo; Microscopic Projection, by Dr. William Hailes, Jr., of Albany; The X Ray from the Static Machine and Some Practical Points in Medicine and Surgery, by Dr. Louis A. Weigel, of Rochester; Skin Diseases, by Dr. Grover W. Wende, of Buffalo; A Needle in the Knee Joint; Suppuration; X Ray; Operation; Cure, by Dr. William Madden, of Brooklyn; Acute Gastro-intestinal Rheumatism, by Dr. Glentworth R. Butler, of Brooklyn; Chlorine in the Treatment of Enteric Fever, by Dr. Reynold W. Wilcox, of New York; Polyomyelitis Anterior Acuta in Children over Five Years, with a Report

of Cases, by Dr. Charles Mason, of Peekskill; The Treatment of Exophthalmic Goiter by Galvanism, by Dr. H. De Valsen Pratt, of Elmira; Hysteria, by Dr. Landon Carter Gray, of New York; The Nervous System in the Pathogenesis of Albuminuria, by Dr. John H. Brownlow, of Ogdensburg; Arterio-sclerosis in its Bearing on Apoplexy, or Cerebral Hemorrhage and Thrombosis, by Dr. Edward D. Fisher, of New York; Tonsorial Hygiene, and the State Control of Barber-shop Sanitation, by Dr. A. Walter Suiter, of Herkimer; Hydrotherapy in Chronic Diseases, by Dr. Simon Baruch, of New York; Abscess of the Lung: The Clinical Data of Two successfully treated Cases, by Dr. Henry L. Elsner, of Syracuse; Pneumonia in Infants: Diagnosis and Treatment, by Dr. William P. Northrup, of New York; The Relation of Classical Literature to Medical Education, by Dr. Charles De La Montayne, of Port Ewen; Nervous Dyspepsia, by Dr. Grace Peckham Murray, of New York; Weak Heart, by Dr. Charles M. Rexford, of Watertown; Lithaemia, by Dr. Bradford C. Loveland, of Clifton Springs; Two Unique Cases of Vesico-vaginal Fistula, by Dr. John O. Polak, of Brooklyn; Operation for the Repair of the Recto-vaginal Septum, by Dr. Ralph Waldo, of New York; The Treatment of Uterine Hemorrhage with Stypticine, by Dr. Herman J. Boldt, of New York; The Relative Merits of the Different Operations for Uterine Suspension, by Dr. John B. Harvie, of Troy; The Advantages of the Suprapubic over Vaginal Coliotomy, by Dr. John W. Whitbeck, of Rochester; The Advantages of Vaginal over Suprapubic Coliotomy in Certain Diseases of the Uterus and Appendages, by Dr. Henry T. Williams, of Rochester; The Death-rate in Abdominal Surgery, by Dr. W. Gill Wylie, of New York; The Relations of Movable Kidney and Appendicitis to each Other, and the Practice of Modern Gynecology, by Dr. George M. Edebohl, of New York; An Experiment in Ovarian Transplantation, by Dr. James H. Glass, of Utica; Conservative Treatment in Diseases of the Ovary and Vermiform Appendix, by Dr. Robert T. Morris, of New York; The Management of Lateral Curvature of the Spine, by Dr. Reginald H. Sayre, of New York; Lateral Curvature and Pott's Disease of the Spine; the Improved Aluminum Corset for their Treatment, by Dr. A. M. Phelps, of New York; Should Tuberculous Sinuses be treated Surgically or not? by Dr. Virgil P. Gibney, of New York; The Treatment of Umbilical Hernia, by Dr. William B. De Garmo, of New York; The Diagnosis and Surgical Treatment of Gallstones, with a Report of Cases, by Dr. Edward W. Mulligan, of Rochester; Intra-ocular Tumors: their Frequency, Prognosis, and Treatment, with Specimens, by Dr. Herman Knapp, of New York; The Present Operation for Senile Cataract, by Dr. D. B. St. John Roosa, of New York; The Surgery of Mammary Cancer, by Dr. Daniel Lewis, of New York; Further Study into the Nature and Frequency of Cancer, by Dr. Roswell Park, of Buffalo; Some Problems associated with Typhoid Fever, by Dr. William Ogler, of Baltimore; The Disinfection of the Alimentary Canal, by Dr. Abraham Jacoby, of New York; A Suture Material Suitable for Abdominal Surgery, by Dr. Robert J. Wilding, of Malone; A New Lap-suture in Abdominal Surgery, by Dr. William E. Butler, of Brooklyn; The Treatment of Boils and Carbuncles, by Dr. William O. Stillman, of Albany; The Limitations of Surgical Work in Country Practice, by George M. McComb, of Frankfort; The Differentiation of the Chronic Forms of Rheumatism, by Dr. Louis F. Bishop, of New

York; Life Insurance from a Professional Standpoint, by Dr. Josiah Hasbrouck, of Port Ewen; An Additional Reason for requiring in Almshouses Measures for the Prevention of Purulent Ophthalmia in Infancy, by Dr. Lucien Howe, of Buffalo; and The Scientific Aspect of the Mind Cure, by Dr. S. A. Russell, of Poughkeepsie. Papers by the following gentlemen have been promised: Dr. Peter A. Callan, of New York; Dr. William S. Cheesman, of Auburn; Dr. Henry H. Deane, of Watertown; Dr. William S. Ely, of Rochester; Dr. John H. Jewett, of Canandaigua; Dr. Clair S. Parkhill, of Hornellsville; Dr. A. D. Rockwell, of New York; Dr. Frank Van Fleet, of New York; Dr. Charles G. Wagner, of Binghamton; and Dr. Hamilton D. Wey, of Elmira.

The Effects of the Spanish-American War.—The *Lancet* for December 31st, in its review of the *annus medicus*, says on this subject:

"Turning to other parts of the world, we have had the Spanish-American war with its striking and dramatic incidents and results, the full effects of which have yet to be realized and harvested. That these will be for the good of humanity and the world at large can not be doubted; and we have only to take account of the inimical feeling and even consternation with which the drawing together of the American and British nations is regarded by foreign powers to see that they, at any rate, realize the meaning and import of such a combination. We heartily congratulate the United States on the successful termination of that war, believing, as we do, that its results will be favorable to the freedom of the oppressed and eventually turn out to be for the benefit of all concerned. The year 1898 is the most eventful to the American Republic since the end of its civil war. For the first time the United States Government finds itself face to face with the problem of dealing with foreign possessions outside its own continent. Considering that a commission is inquiring into the causes and extent of the alleged breakdown of the sanitary and medical arrangements of the late war, for which the United States was apparently unprepared, there is no need to dwell further upon the subject now; but we may add a word to the effect that it is only by the organization and perfecting of all that appertains to a medical service in times of peace that successful results can be attained in time of war. There is no royal road to success in this respect, as this and other countries have had to learn by bitter experiences in the field."

A Miniature Baby.—According to the *Boston Medical and Surgical Journal* for January 12th, there is at present at Gouverneur Hospital a female infant said to be perfect in its development in every respect except as regards size; at the age of two months she weighs but thirty-two ounces and three quarters. When born, her weight was only sixteen ounces.

A Study of Cerebro-spinal Meningitis.—At a meeting of the New York Neurological Society held on Tuesday evening, January 3d, Dr. Lewis A. Conner read a paper based on sixty cases that had been observed in the Hudson Street and New York Hospitals. Every effort had been made to exclude those in which the meningitis was secondary to other processes. Of the sixty, twenty-one occurred in 1897, the year in which the disease was especially prevalent in various parts of the country. Ten occurred during the last two months. One half of all the cases occurred in the spring months, March, April, and May. The youngest patient was a

child of two months, and the oldest a woman of sixty-five years. In only one was there a distinct history of exposure to cold immediately preceding the attack. No two of the patients came from the same family, although two negroes occupying the same room were attacked within a few hours of each other, and both died in a short time. Post-mortem examinations were made in eighteen of the forty-one fatal cases. In the very acute cases there was marked congestion of the meningeal vessels. The exudate was often so slight as to be scarcely perceptible, except in cases that had lasted two weeks or more. The lateral ventricles were often distended with purulent fluid. The greatest involvement of the spinal cord was in the dorsal and lumbar portions, and always on the posterior surface. Microscopical examination showed constant involvement of the subjacent brain tissue. The common involvement of the cranial nerves was also noted. Councilman and his associates, said Dr. Conner, were convinced that the specific cause of epidemic cerebro-spinal meningitis was the *Diplococcus intracellularis*. In the thirty-five cases examined by them the organism was found in all but four, almost exclusively in the pus cells. It was an aerobic bacterium, which grew best on blood-serum agar. It had been previously considered that the *Diplococcus lanceolatus*, or the pneumococcus, was the organism responsible for this disease. Bacteriological examination was made in ten of the cases reported in the paper. In three autopsies in which the culture results were negative only ordinary culture media were used. The *Diplococcus intracellularis* was found in only four of the cases, and the pneumococcus in about the same proportion. All the usual types described were represented in this series. All the fulminant cases were marked by early delirium and coma. Twenty-six ran their course in two weeks, and all ended fatally. There were two of the intermittent type. Thirteen lasted more than a month, and in these cases eleven patients recovered. The longest course was three months and a half. The onset was sudden in thirty-nine cases. The temperature was decidedly irregular, but there were several distinct types. In a number the temperature was normal or subnormal throughout the disease, or up to a short time before death. In a second type the temperature was moderate most of the time. In others the temperature rose gradually and then fell, whether or not recovery took place. These cases resembled typhoid fever somewhat, but not infrequently the highest temperature was in the morning. In the fulminant cases the temperature was sometimes nearly normal for the first few hours. The pulse also varied greatly, independently of the variations in temperature. Retardation of the pulse was not common, and was pronounced in only two cases. Where the symptoms were active an almost constant symptom was a marked increase in the respiration rate. Vomiting was present at some time in over half; in twenty-five it appeared at the onset, and in fifteen only at that time. In fifteen it remained a prominent feature throughout the disease. In no case was the vomiting "projectile." There was more or less pain in all cases, and it was usually in the form of an intense occipital headache, but there was not infrequently pain in the back, limbs, and chest, sometimes especially marked on one side. The reflexes presented a constant feature. More or less rigidity of the muscle of the head, neck, and back was present in almost every case. Rigidity of all the extremities was also common. There was no uniformity about the appearance of the pupils. In one case which ended in re-

covery there was consciousness throughout. In a large proportion delirium and stupor alternated. Some of them were marked by an unusual form of delirium simulating hysteria. Skin manifestations were observed in twenty-five per cent., but the hæmorrhagic eruption was seen in only three of the cases. A distinct leucocytosis was present in most of the cases in which the blood was examined. The spleen was enlarged in twenty-three per cent. In none of the cases of recovery was there disturbance of vision subsequently. In two there was bilateral deafness, but one of the patients recovered completely. In several there were involvements of the joints resembling those seen in rheumatism. In seven pneumonia occurred, and in all of them it developed after the meningitis. Albuminuria was generally an accompaniment of the disease.

St. Vincent's Hospital.—A concert, followed by a dance and supper, was held at the Waldorf-Astoria Hotel on Wednesday evening. It was the first of a series of entertainments in celebration of the "golden jubilee" of the hospital, by which it is hoped to raise money to provide a recent addition to the hospital with proper furniture.

The Italian Pharmaceutical Association of the State of New York was incorporated last week.

The Ninth International Congress of Ophthalmology will be held in Utrecht on August 14th, 15th, 16th, 17th, and 18th. Only the English, French, and German languages can be employed in communications. The registration fee is twenty-five francs. Gentlemen who intend to be present are requested to write to Professor H. Snellen, of the University of Utrecht, stating if they are to be accompanied by ladies and if they intend to present papers.

The Late Dr. Charles W. McManus.—We have been requested to publish the following:

The medical board of the Willard Parker and Riverside Hospitals having learned with profound regret of the death, on January 5, 1899, of Dr. Charles W. McManus, late interne physician to the hospitals, the following preamble and resolutions were unanimously adopted:

Whereas, It has pleased the Almighty to remove by death Dr. Charles W. McManus, interne physician to these hospitals; and

Whereas, Dr. McManus has made for himself in our hospitals an enviable record for conscientious and painstaking work and unremitting zeal in the performance of his duties, and has gained the esteem and affection of his colleagues by his admirable personal qualities; therefore be it.

Resolved, That this board deeply regrets the cutting short of so promising a career at the very beginning of professional life; and be it

Resolved, That we offer to the father of Dr. McManus our deep sympathy in the terrible loss he has sustained in the death of this his only son; furthermore, be it

Resolved, That a copy of these resolutions be transmitted to the board of health, the father of the deceased, and the medical journals, and spread in full upon the minutes of this meeting.

[Signed.]

AND

JOHN ARCHINARD, M.D.

THE recent visitation of yellow fever in New Orleans during the summer and fall of 1897 afforded us a splendid opportunity of studying from a bacteriological standpoint the causation of this disease. The published researches of Sternberg and Sanarelli were of great advantage to us. We followed as closely as we found practicable the technique of these experimenters, and we were not long in making discoveries and reaching a definite conclusion.

The news of the outbreak first reached us in mid-ocean, when casually glancing over a copy of the *New York Herald* of September 7th, belonging to a fellow-passenger. From that time on we had no other idea but the reaching as speedily as possible of our native city, to be on the ground and help the good cause—the study of this dreadful malady—and contribute our mite toward stamping it out forever. We reached New Orleans on September 28th, and forthwith began our labor in the pathological department of the Isolation Hospital and in the Bacteriological Laboratory which the Tulane Medical College so generously puts at the service of the Louisiana State Board of Health to carry on its work.

And here it might be best to begin by mentioning those who have been of assistance to us in our important and difficult task. First, we owe thanks to Dr. J. D. Bloom, house surgeon of the Charity Hospital, for his kind permission to have free access at all times to the Isolation Hospital and its post-mortem house; to Dr. J. H. Vauzie, the visiting physician of the Yellow-Fever Hospital, for his kindness and, at times, valuable help; to Dr. Hamilton P. Jones, resident physician of the institution, for help in various ways, such as collecting blood stoles for us, assisting us at autopsies, in taking notes and making our cultures from the blood and organs, and occasionally, when we were absent from the autopsies, in making cultures and forwarding same to us; to Dr. O. L. Pothier, pathologist of the Charity Hospital, for his uniform courtesy and kindness in the

post-mortem house, making the autopsies at times to suit our convenience best, furnishing us with materials and specimens of organs, and allowing us to take cultures as we suggested and preferred; to Dr. R. S. Woodson, captain United States army, a daily attendant and worker in the laboratory, for his help in making plate cultures, performing comparative tests with various bacteria, under our guidance and at our suggestion, doing a great part of the work of the Widal's test, keeping our cultures alive, assisting us in the animal inoculations and at their autopsies, and in making cultures from them, and in the latter part of his stay with us, in making the animal autopsies for us; to Dr. Ott Lerch, for sundry services, too long to enumerate; to Dr. John Callan and other frequent visitors to the laboratory, for their kind encouragement; lastly, to Dr. John J. Archinard, a young brother and assistant, for the remarkable foresight with which he collected the blood of patients, made autopsies and cultures, and kept the organs of all his cases before our return, and after we had assumed charge, for his constant devotion and assistance, doing whatever we required of him always cheerfully and well, never caring how much humdrum or drudgery there might be in it all, provided it was our wish and for the benefit of science and mankind.

Our work may properly be divided into four parts, all of which are distinct, but which have enough relation together to be presented in the same treatise:

I. SEARCH FOR AND ISOLATION OF THE SPECIFIC GERM OF YELLOW FEVER IN THE CADAVERS OF YELLOW-FEVER PATIENTS, IN THE BLOOD OF THE SICK, AND IN THEIR EXCRETIONS.—For the purpose of avoiding repetition and to show clinically and pathologically the type of our most severe cases of yellow fever, we give below the history and post-mortem notes of one of these, closely observed from beginning to end:

N. B., taken sick September 30, 1897; slight chill; severe headache; anorexia and great pain in muscles of back and limbs; temperature, 103.6° F.; pulse, 110.

October 1st.—Temperature, 104° F.; pulse, 126; tongue very much coated; infected conjunctivæ; great nausea; urine high, colored; specific gravity, 1.020; scanty, thirteen ounces, and a half in twenty-four hours; acid reaction; no albumin; diarrhoea, with dark-colored stools; blood examined for phagocytes; negative result.

2d.—Conjunctivæ more injected; tender, fissured, particularly noticeable; nasal mucous membrane; great nausea; severe headache; urine, twenty-two ounces in twenty-four hours; specific gravity, 1.020; reaction acid; albumin positive, five per cent.; no casts; osmium, temperature, 104.1° F.; pulse, 98.

3d.—General symptoms more severe; temperature, ten per cent.; great anorexia and delirium; no phagocytes; urine, twenty-four ounces; specific gravity, 1.020; reaction acid; albumin positive, five per cent.; no casts; osmium, temperature, 104.4° F.; pulse, 88.

7th.—Great anorexia; severe headache; vomit, with a few, from 76 to 96, phagocytes; temperature, 103.8° F.; reaction of urine, alkaline; albumin, positive, five per cent.; no casts; vomit.

5th.—State of collapse; temperature, 102° F.; pulse,

* This article was intended for the meeting of the American Medical Association in Denver. Owing to the outbreak of the war the writer foresaw that it would be impossible for him to attend and meet, and he therefore read the article before the Louisiana State Medical Society, in New Orleans, on May 12, 1898.

SS; almost complete suppression of urine; albumin, sixty per cent.; beginning jaundice; black vomit very severe.

Ult.—Projectile vomiting; complete anuria; uræmic coma; convulsions; death 11 A. M.

Autopsy six hours after death; body well nourished; rigor mortis well marked; hypostatic congestion marked in dependent portion of body; integument saffron hue; conjunctivæ yellow; dry omentum; liver pale, boxwood color, very friable; gall bladder filled with bile; left kidney slightly congested with fatty infiltration; right kidney enlarged, much more congested, and less fatty; stomach, numerous extravasations upon mucosa, especially pyloric end, much congestion, serous coat of yellow color; heart and lungs showing steatosis; pericardial sac filled with fluid; spleen normal, bladder empty; cultures from all organs and our bacillus isolated therefrom.

Our studies comprise the cultures obtained from sixty autopsies: from the life blood in five cases; from the exhaled breath in twelve cases; from the sweat or scraping of the surface of the body in twelve cases; from the black vomit in four cases.

Of the sixty autopsies, eight were made and cultures obtained by Dr. John J. Archinard; one was made by Dr. Woodson and Dr. John Archinard at the Jackson Barracks. The other fifty-one were made at the Isolation Hospital. At nearly all of the latter we were present ourselves and made our own cultures. In the first cases, besides taking cultures immediately after section of the body, blood from the cadaver was drawn into sterilized pipettes and large pieces of organs, principally liver, spleen, kidneys, were wrapped up in anti-septic dressings, taken along and incubated for twenty-four or forty-eight hours, according to Sternberg's recommendation; after which, from their interior, cultures were made and animals inoculated. As this inoculated blood and organs did not seem to give us better results, we soon abandoned this procedure.

Our mode of taking cultures at autopsies was as follows: Immediately after section the organs were exposed one at a time, surface cauterized with a piece of flat iron heated to whiteness and a stab made with a sterile, lance-shaped platinum needle; the blood, organ juice, and small *débris* of tissue remaining adherent to the needle were planted on the surface of an agar tube or in lactose bouillon. After a short time bouillon inoculation was done away with on account of the difficulty of transporting same. The cultures brought to the laboratory were then incubated for twenty-four, sometimes forty-eight hours, and then allowed to grow outside of incubator; later on they were plated and the various colonies isolated.

Cultures were taken at each autopsy from the following part: Peritoneal exudate, pericardial fluid; blood from the heart; blood and juice of the lungs, liver, kidneys, spleen; bile from the gall bladder; excretions from the stomach, and occasionally from other parts.

With the exception of two cases, our cultures always gave us a number of bacteria, and often the plating had to be repeated several times before pure colonies could be obtained. The bacteria found consisted chiefly of our bacilli in association with the coli communis, frequently with the *Proteus vulgaris*, sometimes the *Staphylococcus aureus* and *citreus*, occasionally, though rarely, the *Streptococcus pyogenes*. Of the sixty autopsies held, six were rejected, as they did not show the anatomical lesions of yellow fever. In a few other cases little or no growth was obtained from the original culture tubes. In several instances some of the tubes in our laboratory got so mixed up that it was impossible for us to positively identify them, and all these were rejected. On account of these discarded ones the number of autopsies from which cultures were available for our purposes was reduced to thirty-nine. In these thirty-nine cases, we were able to obtain our bacilli thirty-two times; in two cases in a pure condition. In the thirty other cases in association, as stated above. In seven cases we were unable to isolate any bacilli resembling ours.

Five specimens of live blood were obtained from veins at the bend of the elbow, with aseptic precaution from typical cases of yellow fever, on the third, fourth, and sixth days of the disease; six cubic centimetres were taken from each case and mixed up in an Erlenmeyer's flask with five cubic centimetres of sterile lactose bouillon, the whole incubated for forty-eight hours and then plates made therefrom, and a portion used for the inoculation of animals. In two of these cases the growth showed pure cultures of our bacilli; in two other cases, we were able to obtain pure cultures after passing same through animals; in one case the result was negative.

What we call the exhaled breath was obtained by fixing some sterilized cotton in an inhaler and binding same over patient's mouth and nose for from fifteen minutes to an hour; the cotton was afterward planted in lactose bouillon, incubated forty-eight hours, and then plated. In all these cases the patients showed typical symptoms of yellow fever from the fourth to the twelfth day of disease. We were able in twelve such cases to obtain our bacilli only twice.

The sweat and scraping from the body of patients were also investigated. For this purpose a piece of sterilized cotton was rubbed over the face, neck, and upper part of thorax; bathed in perspiration of patients in advanced stages of the disease, and planted in bouillon as above. Of the twelve cases so studied, two gave us the bacilli.

We have used the word bacilli always in speaking of the micro-organism we isolated, because for a while we thought they were two distinct micro-organisms, though morphologically they appeared identical; but some slight variation in their culture development made us feel that it was best to keep them separate. Later experimentations and the passage through animals showed

that we were dealing with one and the same bacillus, for both answered identically to all the culture tests known. Our two organisms we called for convenience sake bacillus A and bacillus B. Bacillus A was obtained from colonies which appeared nucleated on gelatin plates, whereas bacillus B was obtained from colonies almost identical but not nucleated. Later on we observed, however, that bacillus A, when in the pure state, would as often give rise to non-nucleated colonies as to nucleated ones, and the reverse appeared also for bacillus B. The fact of the matter is, we believe, that at first our cultures of bacillus B were somewhat contaminated with some saprophytic bacteria, and that accounted for the cultural variation which it showed when compared with bacillus A.

In our experiments we obtained bacillus A twenty-nine times; and in four cases we obtained from the same plates both bacilli A and B. The fact noted above, of nucleated and non-nucleated colonies, we have noticed frequently since, when cultivating the *Bacillus icteroides* of Sanarelli on gelatin plates.

The character of our bacillus may be described as follows: A short thick rod measuring from two to four micromillimetres in length by about half the breadth, showing in different media marked pleomorphism: it is very motile, as much so as the *Bacillus typhosus*. It has end flagella very much like this bacillus, stains well in all watery solutions of basic aniline dyes, unstains by Gram's method. It is aerobic—i.e., it grows best in ordinary atmosphere—but is facultative anaerobic; i.e., grows when deprived of oxygen and in the presence of hydrogen. It grows readily in all known neutral or weakly alkaline media, both solid and fluid; it produces very slowly, or not at all, acidity in these media: it grows best at 37° C., but grows also, though more slowly, at ordinary laboratory temperature from 18° to 22° C. In peptone bouillon it grows fairly well, but best in lactose bouillon, causing a general turbidity of the fluid, but no scum and no deposit at the bottom. It causes a slight fermentation in lactose bouillon generally, but occasionally produces no fermentation in this media; in glucose bouillon it produces marked fermentation; in milk it grows readily without producing coagulation even after weeks; in litmus milk it causes a slight acidity, but only very slowly; in Dunham's solution it produces no indol, even after the addition of nitrite, but does so after the addition of an acid; on potatoes it produces a whitish yellow transparent growth; on blood serum it grows readily, but shows nothing characteristic; on the surface of gelatin it grows readily, showing a whitish transparent growth; on gelatin plates the individual colonies show under the low power of microscope as a gray or yellowish gray rounded form, iridescent and often containing a nucleus which may be central, but is at times peripheral; this nucleus is generally darker than the rest of the colony and is surrounded by a light halo; in stick culture it grows

all along the stab, but more luxuriantly at the surface. It does not liquefy gelatin. On the surface of agar its growth is almost transparent when young. As it grows older it gets whiter. Older colonies at the bottom of the tubes, near the water of condensation, show marked raised points, darker than the rest of the growth, which resemble nuclei. The characteristic growth described by Sanarelli in old cultures of his *Bacillus icteroides* in agar, when growing partly in and partly out of the incubator, has been observed by us, but we have been able to obtain this characteristic growth only when these cultures were quite old. It is typically agglutinated by the blood of yellow-fever patients or of persons who have recently had yellow fever, as will be mentioned later. Inoculated in animals, guinea-pigs and rabbits, it gives rise to typical symptoms, and when inoculated in sufficient quantity causes death, and sometimes very quickly. The pathological lesions found are characteristic, and it is found in the blood and organs of animals dying from its effect, and can be recovered from these in pure cultures.

II. RESULTS OF ANIMAL INOCULATIONS.—We give results of injections in guinea-pigs and rabbits, together with post-mortems of these animals. The rabbits were inoculated in the veins of the ears and the guinea-pigs subcutaneously. The material used for inoculation was always a bouillon culture of the bacilli from eighteen to twenty-four hours old, and kept at 37° C.

Rabbit No. 18, weight 1529 grammes, inoculated with six cubic centimetres bouillon culture of our bacillus (A), died during night of same day; weight after death, 1470 grammes. Autopsy showed blood-vessels of heart and diaphragm congested; heart full of blood; lungs pale; intestines very much congested; stomach full of food; mucous membrane congested and showing ecchymotic spots; liver fatty and friable; spleen enlarged; gall bladder containing a large quantity of dark bile; kidneys pale and fatty; bladder filled with non-albuminous urine. Cultures made from blood, heart, liver, spleen, showed typical growth of bacillus A.

Pig No. 18, weight 475 grammes, inoculated subcutaneously with twelve cubic centimetres of a lactose bouillon culture of our bacillus A, eighteen hours old, at 37° C., showed shortly afterward signs of depression, temperature rose the next day to 41° C., animal remained quiet and was unwilling to move or eat; he died three days after. Autopsy, immediately after death, showed the blood-vessels of pleura, peritoneum, diaphragm and heart surface very much congested; heart full of dark blood; lungs pale, otherwise normal; liver congested, fatty and friable; kidneys congested and fatty; bladder contained some albuminous urine; stomach and small intestines very much congested with ecchymotic spots in mucous membrane; viscera full of black fluid resembling black vomit. Bacillus A obtained from cultures made of each organ.

Rabbit No. 19, weight 1,990 grammes, injected intravenously with six cubic centimetres of an eighteen-hour-old bouillon culture, our bacillus B; died during the night; post-mortem lesions same as those of rabbit No. 18. Animal was gravid. Cultures as made from all organs and also from fœtus gave us pure cultures of bacillus A.

Pig No. 19, weight 390 grammes, inoculated the same day as pig No. 18, but with bacillus B instead of A; died on the same day as pig No. 18 and showed identical post-mortem lesions, and from all its organs we were able to obtain pure cultures of bacillus B.

Rabbit No. 17, weight 1,950 grammes, inoculated at same time as rabbits Nos. 18 and 19, but with *Bacillus icteroides* of Sanarelli; died the same day as rabbits Nos. 18 and 19 and showed the same lesions; its organs gave pure cultures of the bacillus Sanarelli.

Pig No 17, weight 450 grammes, inoculated with twelve cubic centimetres *Bacillus icteroides* (Sanarelli) on same day as pigs Nos. 18 and 19; died within a few minutes of the latter animals on the fourth day after inoculation, presenting identical post-mortem changes and giving pure cultures from its organs of *Bacillus icteroides*.

Pig No. 20 inoculated with five cubic centimetres of a bouillon culture of bacillus A; became sick, lost appetite, had fever up to 42° C., lost weight, but after three or four days became more lively and began eating again.

Rabbit No. 20 inoculated intravenously with two cubic centimetres bacillus A; lost weight and appetite, was feverish for a few days, afterward recovered appetite and became lively again, and only died thirty-one days after inoculation, showing tuberculosis of lungs and liver. Cultures made from organs and blood remained sterile.

Rabbit No. 21 inoculated intravenously with two cubic centimetres of a bouillon culture of Sanarelli's bacillus; became sick like above, but after a few days recovered and kept alive.

Pig No. 21, inoculated with five cubic centimetres of a bouillon culture of *Bacillus icteroides* (Sanarelli); remained alive after showing for a few days indications of weakness.

III. COMPARATIVE TESTS BETWEEN BACILLUS SANARELLI AND OUR BACILLI A AND B.—The following is a comparative table of our bacilli A, B, and *Bacillus icteroides* of Sanarelli from tests made by us:

<i>Bacillus icteroides</i> (Sanarelli).	Bacillus A.	Bacillus B.
1. Aerobic and facultative anaerobic.	Aerobic and facultative anaerobic.	Aerobic and facultative anaerobic.
2. Short rod: 2 to 4.	Short rod: 3 to 4.	Short rods 2 to 4.
3. Actively motile.	Actively motile.	Actively motile.
4. Stains readily with aniline dyes; does not resist Gram's method.	Stains readily with aniline dyes; does not resist Gram's method.	Stains readily with aniline dyes; does not resist Gram's method.

<i>Bacillus icteroides</i> (Sanarelli).	Bacillus A.	Bacillus B.
5. Does not produce acid in Dunham's solution, even after addition of nitrite; slowly sometimes after addition of acids.	Does not produce acid in Dunham's solution even after addition of nitrite; slowly sometimes after addition of acids.	Does not produce acid in Dunham's solution even after addition of nitrite; slowly sometimes after addition of acids.
6. Slight odor of indol.	Slight odor of indol.	Slight odor of indol.
7. Does not coagulate milk.	Does not coagulate milk.	Does not coagulate milk.
8. Produces acid, but very slowly.	Produces acid, but very slowly.	Produces acid, but very slowly.
9. Ferments glucose rapidly.	Ferments glucose rapidly.	Ferments glucose rapidly.
10. Ferments lactose slightly, sometimes not at all.	Ferments lactose slightly, sometimes not at all.	Ferments lactose more readily.
11. Grows in gelatin, does not liquefy this medium.	Grows in gelatin, does not liquefy this medium.	Grows in gelatin, does not liquefy this medium.
12. Growth on potatoes almost transparent.	Growth on potatoes almost transparent.	Growth on potatoes almost transparent.
13. Produces cloudiness without deposit or scum in bouillon.	Produces cloudiness without deposit or scum in bouillon.	Produces cloudiness without deposit or scum in bouillon.
14. Growth on gelatin whitish transparent; under the microscope (low power) grayish or yellowish-gray, iridescent, and often containing nucleus.	Growth on gelatin whitish transparent; under low power grayish or yellowish-gray, and often contains nucleus.	Growth on gelatin whitish transparent; under low power grayish and sometimes nucleated, at others not.
15. Growth in agar almost transparent when young, porcelain-like when older; at bottom of tubes especially, colonies show marked nucleation when older.	Growth in agar almost transparent when young, porcelain-like when older; at bottom of tubes especially, colonies show marked nucleation when older.	Growth in agar almost transparent when young, porcelain-like when older; at bottom of tubes especially, colonies show marked nucleation when older.
16. Agglutinated by yellow-fever blood.	Agglutinated by yellow-fever blood.	Agglutinated by yellow-fever blood.

Characteristic growth in and out of incubator, as described by Sanarelli, has never shown, except in very old cultures of our bacilli A and B, and the same may be said of the *Bacillus icteroides* grown by us.

Comparative tests to show growth in agar cultures of other bacilli afterward made sterile and culture medium allowed to cool, and then inoculated with our bacilli, and *Bacillus icteroides* of Sanarelli gave us negative results with all. In one or two instances we have noticed that some form of laboratory mold favor the growth of bacillus A, bacillus B, and bacillus Sanarelli.

IV. SERUM REACTION WITH BACILLUS ICTEROIDES AND OUR BACILLI A AND B.—Pfeiffer's demonstration of the phenomena of agglutination of microbes which consist in the peculiar clumping and stoppage of motion in cultures of before motile bacilli by the addition to those cultures of a small amount of the blood serum of animals previously inoculated with these bacilli, served as a new departure in bacteriology, and enabled us to apply this method for the purpose of aiding in the diagnosis of previously obscure cases.

Widal discovered that the serum of patients afflicted with typhoid fever could agglutinate the *Bacillus ty-*

phosis; he laid down definite and reliable rules for the application of this method to the diagnosis of the disease. Later Wyatt Johnston, of Montreal, showed that a drop of dry blood, afterward properly dissolved and diluted, could be used as efficiently as fresh serum, and we are thus enabled to apply the rules of serum diagnosis to typhoid fever in municipal and board of health laboratories.

Following in those footsteps we analyzed blood from yellow-fever patients, from healthy individuals, and from cases in various other diseases, for the purpose of applying the Widal test to the *Bacillus icteroides* recently isolated by Sanarelli in yellow-fever cases and to an identical bacillus found by us in a number of 1897 fever cases. The work done in a hundred cases on this subject, in collaboration with Captain R. S. Woodson, M. D., United States army, then stationed in New Orleans, and with our assistant, Dr. John J. Archinard, we submitted to the Orleans Parish Medical Society at its meeting, January 22d, and our paper read then has been published in the February number of the *New Orleans Medical and Surgical Journal*. Since then we have continued and extended our labor, in conjunction with Dr. John J. Archinard, Dr. Woodson having removed to Johns Hopkins Laboratory, and we have added a number of cases to those already observed, which make the results obtained still more interesting and important. A synopsis of all this is here submitted and conclusions drawn therefrom.

We used the blood of fifty cases of yellow fever in the acute stages and during recent convalescence. Twenty of these are of little value to us and should be discarded, as both the bacillus of yellow fever and that of typhoid fever were agglutinated, owing to the fact that the blood was used in too concentrated a form in making the test (one in five, when it should have been one in twenty, or even one in forty). In the remaining thirty cases, when the proper dilution of blood was made (one in forty), we obtained the characteristic clumping of the yellow-fever bacillus in twenty-four cases, a proportion of eighty per cent. If now from these thirty cases we omit three cases where no clumping with the bacillus of the yellow fever was obtained, and a characteristic clumping with the bacillus of the typhoid fever, cases which were thought to be cases of secondary fever following yellow fever, but which were probably simple cases of typhoid fever, our proportion of positive cases would be $88 \pm$ per cent. In the yellow-fever cases, omitting the three just referred to, the clumping both of typhoid and of yellow fever bacilli occurred five times, but four of those cases were cases of yellow fever with a previous history of typhoid, or typhoid case with a recent history of yellow fever. In only one case did we get such a double reaction without the previous history of typhoid, and in that case it was not possible to ascertain the previous history. In five or six of those cases, where the blood was taken early in

the disease (second day), the agglutination was well marked. This seems to point to the fact that the test would be more useful in the early stages of the disease, indeed where it is most needed. Our number of cases has been too few to accept this question as settled. Experiments on a large scale are necessary before concluding finally.

Twenty cases of malarial fever were examined. Plasmodium was found in thirteen cases and not sought for in one case with a distinctive history of malarial fever. In two other cases plasmodium could not be found, though the clinical history was undoubtedly malarial intermittent. Seventeen cases in all, which gave negative results with the *Bacillus icteroides*. In three cases agglutination was obtained: these cases showed no plasmodium, and were all cases of continued malarial fever of five, six, and ten days' duration, occurring in the midst of the epidemic, one of them being an Italian.

Thirty-three cases of typhoid fever were examined; twenty-five cases gave negative results with the *Bacillus icteroides*, and positive results with the *Bacillus typhosus*. In six cases the reaction with both bacilli were obtained; but four of these cases gave histories of recent yellow fever or of yellow fever in 1878. In the other two cases no history of yellow fever could be obtained. In only one case was it positive with the yellow-fever bacillus and negative with the typhoid.

The blood of thirty cases of various diseases were submitted to the test—such as scarlet fever, tuberculosis, acute diarrhoea, alcoholism, chronic dysentery, measles, tertiary syphilis, diphtheria, cancer of the stomach, leprosy, acute jaundice by obstruction, chronic jaundice, nephritis, pneumonia convalescent, cirrhosis of the liver. All gave negative results.

Twenty cases of normal blood coming from individuals who had never had yellow fever, some of them foreigners, gave negative results with the test. This rather limited number, however, was deemed sufficient on account of the uniformity of the results.

To test how long the blood in yellow-fever cases retained its agglutinative power, we tried the blood in ten cases of fever of 1897 who had been well for several weeks, and obtained agglutination in all but one. Also the blood of ten cases of persons who had had well-marked attacks of yellow fever in 1878, and we obtained agglutination with the yellow-fever bacillus in all but one. A number of cases who had had yellow fever in epidemics previous to 1878 (1853, 1867, and 1869) gave us negative results.

Two cases who during the summer had had dengue in San Antonio kindly consented to let us use their blood for our test. In both of them the tests were negative. Ten cases of dengue with eruption, from Galveston, gave us negative results, and will later on apply the test to these.

We can summarize our results as follows:

By the dried blood method eighty per cent. of the

cases of yellow fever of 1897 agglutinated the *Bacillus icteroides*; nearly twenty per cent. of the cases showed negative. In our typhoid cases with no history of yellow fever the test is almost uniformly negative. In malarial fever whenever plasmodium could be obtained from the blood proving the positive diagnosis of malaria the results of the test were negative. In a number of cases of other diseases the tests were almost always negative. Over ninety cases of normal blood, or blood taken from diseases other than yellow fever, in persons who had never suffered with yellow fever, gave us only four positive results, and indeed in these four cases there is a remote possibility of previous yellow fever.

We would like to emphasize again the fact that our experiments, though pointing to a safe and reliable method of making a diagnosis of yellow fever, do not absolutely settle the question. Experiments should be carried on in a much larger number of cases and by different observers before accepting as final the serum diagnosis of yellow fever.

Conclusions.—1. In a large proportion of autopsies (thirty-two times in thirty-nine) of yellow-fever cases of 1897, in New Orleans, a bacillus was found either in a pure state (two times) or in association (thirty times), similar to the Sanarelli *Bacillus icteroides*. This bacillus has some points in common with the coli communis, but differs from it in some of its essential characteristics.

2. In live blood taken from the veins of the elbow, in well-marked cases of yellow fever, we were able to isolate our bacillus four times in five cases.

3. In the exhaled breath mixed up with secretions from the mouth and nose (sometimes bloody) we isolated our bacillus twice in twelve cases.

4. In the scrapings of the surface of the body of the sick, principally face, neck, in upper part of thorax, we isolated our bacillus two times in every twelve cases.

5. Our bacillus injected intravenously to the rabbit, and subcutaneously to the guinea-pig, in large doses, from five to ten cubic centimetres of a bacillus culture, is always fatal, and sometimes very quickly. In smaller doses (one to two cubic centimetres) the animals are made sick, but generally recover. The animals that die show characteristic lesions of the liver, kidney, and stomach. Cultures from these organs give pure growths of the inoculated bacillus.

6. Our bacillus is identical in almost every respect with Sanarelli's *Bacillus icteroides* obtained from himself, and from Dr. Sternberg, but differs somewhat in its cultural aspects from Sanarelli's description of his bacillus.

7. The blood of yellow-fever cases or of recent convalescents from this disease agglutinates the *Bacillus icteroides* of Sanarelli, and also our bacillus in over eighty per cent. of the cases in the proportion of one part of serum for forty of culture within one hour.

In less than twenty per cent. the reaction does not take place.

8. The blood of typhoid and dengue with eruption and malaria fever when properly diluted, 1 in 40, does not agglutinate the *Bacillus icteroides* or our bacillus except in exceptional instances.

9. The blood from a number of diseases other than yellow fever when properly diluted, 1 in 40, does not react on the *Bacillus icteroides* or our bacillus.

10. Normal blood properly diluted, 1 in 40, does not agglutinate the *Bacillus icteroides* or our bacillus.

11. The blood of persons who have had yellow fever seems to retain its agglutinative power for a number of years. The great majority of the cases tested by us who had had yellow fever in 1878 gave the reaction. Those who had had yellow fever previous to 1878 gave us a blood which possessed no agglutinative power with *Bacillus icteroides* or with our bacillus.

PRELIMINARY REPORT ON THE RESULTS OF BLOOD EXAMINATIONS AT CAMP WIKOFF, AUGUST AND SEPTEMBER, 1898.

By JAMES EWING, M. D.

DURING the five weeks, August 21 to September 24, 1898, the writer was detailed by Surgeon-General Sternberg to render what assistance blood examinations might give in the diagnosis of tropical and other fevers among the troops from Santiago arriving at Camp Wikoff. A preliminary report of the results of this work has been prepared as follows:

I. STATISTICAL.—The report covers 782 examinations made at Camp Wikoff, seven cases kindly furnished by Dr. Charles Norris, from Swinburne Island, New York city, and eleven cases from miscellaneous sources in New York city. These 800 examinations are all, for the writer's convenience in the subsequent treatment of the material, here considered together.

Of these cases, 605 proved to be of malarial nature. To these may be added 10 cases of typhoid fever developing in malarious subjects, and in which the presence in the blood of pigmented leucocytes and severe anæmia were evidences of recent malarial infection, which was also distinctly indicated by the clinical history.

In the 605 cases of malaria, the plasmodia were found in the blood in 335 cases, while in 270 cases the diagnosis was based upon the clinical history and the discovery in the blood of evidences of malarial infection. These evidences of malarial infection in the blood consisted (1) usually in the presence of intracellular bodies so much affected by quinine that their exact type could not be positively determined; or (2) in the presence of typical pigmented leucocytes; or (3), in chronic cases of distinct clinical character, in the presence of marked anæmia.

In 335 cases in which organisms were seen, the signet-ring form only of the *estivo-autumnal* parasite was found in 88 cases; crescentic bodies only in 131 cases; and both rings and crescents in 27 cases. The *estivo-autumnal* parasite was associated with the tertian parasite in 12 cases. The cases in which the *estivo-autumnal* parasite was found number in all 261.

The tertian parasite alone was found in 74 cases, associated with the *estivo-autumnal* parasite in 12 cases, or in all in 86 cases.

Four cases, which were probably of the quartan type, were encountered, but no rosettes were seen in the blood, and the diagnosis was not certain. They were classed as cases showing no organisms.

The blood was examined in 159 cases of typhoid fever, in 40 of which there were evidences of recent malaria, as above explained.

Table of Cases.

Total classified,							

From the above summary, it appears that about eighty per cent. of the cases of Cuban malarial fever are of the *estivo-autumnal* variety, twenty per cent. of the tertian type, and of these about four per cent. show double infection with both parasites, while quartan fever would seem to be very rare.

II. ETIOLOGY.—It is probable that ninety-five per cent. of the patients in the Montauk General Hospital suffered in some form from malaria. A very large proportion of those who slept on the ground in the trenches and swamps about Santiago suffered from some form of fever. It appeared distinctly from the stories of patients that the greater the exposure in this respect, the more certain and virulent the infection. It was reported that every one of a group of men who slept on the ground at a certain particularly noxious spot died in Cuba of pernicious malaria.

Several patients who were early located on the higher ground claimed to have suffered only from "mountain fever," but their blood at Montauk contained crescents.

The earliest dates of beginning illness, as noted in the Montauk cases, were July 10th to 12th (in one case, July 5th), so that a week or ten days seemed necessary

for the development of the disease in any large number of men.

Many of the most intelligent patients were closely questioned about the prevalence of mosquitoes, but the evidence obtained was unsatisfactory, as some admitted that the mosquito was to them a constant pest, while others claimed never to have noticed its presence. Every one, however, noticed and complained about the putrid exhalation of the soil, and seemed to regard this as the dangerous element.

It was a very evident fact that the negro troops not only contracted the disease in fewer numbers, but also withstood the infection much better than the white men. The writer did not see a single fatal case of uncomplicated malaria in a negro, and, as a rule, the fresh and untreated cases showed a very moderate number of organisms in the blood.

III. SYMPTOMATOLOGY.—Most cases described their illness as beginning with a chill of moderate severity, often preceded for a few hours by headache or general pains. Severe chills were nearly always referable to the tertian parasite.

The initial chill of relapses was sometimes described as more severe or as less severe than the first chill, or as wanting altogether. Many relapses in *estivo-autumnal* fever at Montauk occurred without chills, but short chills were rarely absent in the tertian cases. In a moderate number of cases, instead of a chill, the patient was seized with violent vomiting, sometimes of blood.

In some fatal cases, *estivo-autumnal*, the discharge of a new brood of parasites was marked by no symptoms, except a slowly rising temperature and general collapse. Some cases died during the discharge of a new brood with a falling temperature.

With tertian cases the temperature usually reached its highest point in six to twelve hours; in the *estivo-autumnal* cases usually not before the middle or end of the second day.

In the tertian cases no specially peculiar symptoms were noted during the rise of temperature. In the *estivo-autumnal* cases the rise of temperature was often marked by a slowly progressing nervous disturbance, often reaching coma. This coma differed in onset and character from the sudden coma occurring in many other cases.

The sweating and fall of temperature were profuse and rapid in the tertian cases; but in the others the sweat was often slight, or occurred only after the administration of quinine in large doses, and the temperature often required several days for full defervescence. On the other hand, some severe paroxysms of *estivo-autumnal* infection were promptly aborted by large doses of quinine, and the temperature became normal and the blood free from parasites in twenty-four to thirty-six hours. Such cases were indistinguishable clinically from tertian infection with moderate initial chill.

The histories in many severe cases indicated that

the first attack lasted about a week, the temperature reaching its highest point on the second or third day, thereafter rapidly declining till the seventh or eighth day. Often a second paroxysm, of greater severity, followed almost immediately, and continued for a similar period. At Montauk there were rather numerous examples of these typical weekly recurring attacks. In the blood such cases usually showed the signet-ring forms for the first two or three days, young crescents on the third or fourth day, and adult crescents from the fifth to seventh days. A period covering the second to fourth days, with or without fever, was sometimes seen, during which no organisms could be found in the blood. These cases were actively treated with quinine.

It was a common impression that severe or untreated Cuban malaria is fatal in the third of these recurring attacks. Several fatal cases in the third attack were seen at Montauk.

The administration of quinine shortened many of the longer attacks to four or five days, and, treatment being continued, relapses were absent or mild, or exhibited an irregular remittent or intermittent fever.

The course of the fever in these fresh or old æstivo-autumnal infections exhibited the types of tertian, quotidian, remittent, and irregular fevers. Most of the cases of remittent fever of the present series were the result of disturbed paroxysms of the æstivo-autumnal infection.

A striking characteristic of the æstivo-autumnal fever, observed also in some cases of grave tertian infection, was the completeness of the patients' improvement, as judged by their subjective symptoms, during the intervals between attacks. In several fatal cases (130, 285, 295, 793) it appeared that the patient had avoided taking quinine after the subsidence of the fever, in Cuba or on the transport or at Montauk, to be seized shortly by a paroxysm of greater severity than usual, and which was fatal. The failure in these cases to continue treatment with considerable doses of quinine for some weeks after the apparent cure was undoubtedly responsible for many unnecessary fatalities, and the essential importance of this precaution can not be too positively urged.

In none of these fatal cases was the blood examined during the quiescent interval, but in many cases in which crescents were found during afebrile periods the patient suffered later very severe paroxysms, and it can not be doubted that similar signs persisted in the blood of the others. It follows, therefore, that as long as crescents persist in the blood, active treatment should be continued, and indeed for some time thereafter.

The cerebral type of the disease was the most frequent form of the severe seizures.

In fifty-four cases the blood was examined during or shortly after a period of coma. In the blood of these cases, crescent alone were found in thirty-three instances, ring alone in eleven, both rings and crescents

in two, tertian parasites in five, both æstivo-autumnal and tertian parasites in two, and no parasites fully identified in eleven.

Most of the cases in which no organisms are reported were belated cases of mild and transient coma in patients who had been receiving large doses of quinine. The negative finding in other instances of this group, however, indicates beyond a doubt that *the parasites are occasionally very scarce and very difficult to find in the blood during periods of deep coma*. In many of the cases in which crescents were finally found the search was successful only after one and two hours.

Of the eleven cases of coma in which rings alone were found, ten died, and the surviving case was only saved by the most heroic treatment. On the other hand, among thirty-three cases showing crescents only, there were but three fatalities. This comparison indicates a striking difference in the prognosis in cases of coma. The appearance of the early forms of the parasite in large numbers indicates a recent sporulation, and when coma results from the development of a new brood of parasites, it appears to be a very unfavorable condition. When coma supervenes at other periods of the cycle, it appears from the above data that the prognosis is very much more favorable.

According to the clinical character of the coma, these cases appeared to fall into two distinct classes:

1. The discharge of a new brood of parasites was often accompanied by a rise of temperature, gradual loss of consciousness, and slowly deepening coma. After a period of one to three hours the patients were usually in complete stupor and could not be roused. As already stated, most of them died, quinine proving ineffectual. The blood in these cases nearly always showed a large number of young rings.

2. Of the larger group of cases, many were brought to the hospital in coma, having been suddenly prostrated, with loss of consciousness, and with or without spasms or convulsions. Several such attacks developed suddenly in partly cinchonized patients in the wards. At the height of the coma the patient usually presented the typical appearance of "coma vigil," with nearly complete stupor, open eyes, pale sweating skin, stertorous breathing, a full pulse, fever, and pupils reacting to light. The blood in these cases contained crescents, sometimes tertian parasites, but few or no rings. Such conditions were nearly always relieved by large subcutaneous injections of quinine, or, if failing to respond, the stupor became complete, the reflexes were abolished, and the patient died. The result in cases of coma was seldom in doubt longer than twenty-four hours.

Some of these attacks of coma were mild and of short duration. In one case (335) the patient, while sitting up in bed smoking, three times in five days suddenly became unconscious, his pipe fell to the floor, and he remained stuporous for three or four hours. At the end of that period he would wake up, at once pick up his

pipe, and resume smoking. Crescents only were found in the blood during these seizures. An embolic process seems to be the only probable origin of such phenomena.

A considerable number of cases presented symptoms typical of meningitis, with marked rigidity of neck and limbs, and retarded pulse. The patients usually recovered promptly after the injection of quinine.

A great variety of milder nervous symptoms was observed, including localized neuralgias, spasms, aphasia, and mild hemiplegia; but these cases never failed to give a distinct history of a recent acute febrile attack.

Of the *algid type* no clear examples were seen, although many of the fatal cases died with low, but not subnormal, temperatures.

The *gastric type* of the disease was illustrated by many cases of violent and persistent vomiting, which occurred with or without fever. The response of many of these to subcutaneous injections of quinine was remarkable. In a few instances the initial paroxysm was marked by, or consisted in, considerable hæmatemesis. *In these cases, for some hours after the hæmorrhage, the parasites were usually scarce and difficult to find in the blood.*

In a few cases, showing crescents, the attacks of vomiting recurred every four days.

Intestinal symptoms were very common in the malarial cases at Montauk.

Simple diarrhœa was or had been a nearly universal complaint, and was usually referable to improper food.

Severe diarrhœa with mucous stools was a specially prominent complaint in sixty-seven patients who appeared to be suffering from *catarrhal colitis*.

Dysentery, or *ulcerative colitis*, was observed in thirty-six cases of malaria. It was probably much more frequent in occurrence than is indicated by these figures, for in the absence of prominent symptoms a previous colitis might have been overlooked in the history.

In the above cases of dysentery, crescents were found in the blood in nine cases, rings in six, tertian parasites in three, and both varieties of parasites in one case.

In seventeen cases the malarial element had been rendered quiescent by quinine, and no distinct parasites were found.

In nine of the active malarial cases the *Amœba dysenterica* was found in the stools. These amœbæ measured from forty to fifty-five micromillimetres in length while active, and fifteen to twenty-five micromillimetres in diameter when contracted to the spheroidal form after death. They were sometimes present in enormous abundance, especially in active untreated cases discharging much bloody mucus. In the more purulent stools they were less abundant, and in the entire absence of mucus the amœbæ could not be found at all. They were once identified in the aspirated fluid from a complai-

ing perirenal abscess, but no hepatic abscesses were seen in the cases at Montauk. The amœbæ were usually associated with streptococci, and in several cases enormous numbers of infusoria, *Megastoma entericum*, were found.

There was no clinical or gross anatomical evidence that these inflammations of the colon were referable to the malaria.

In very few cases of dysentery was an active malarial element suspected before the examination of the blood, as the malarial symptoms were masked by, or mistaken for, the symptoms of colitis. Seven cases were fatal, in all of which the malarial infection was severe. Most of the other cases recovered or were transferred to other hospitals.

In forty cases of continued fever, with marked evidence of recent malaria, diarrhœa was referred to infection with typhoid fever.

Pulmonary symptoms were rather infrequent. A few cases of bronchitis were seen, and two cases of pneumonia—one fatal—developed during the course of chronic malaria, and one case of pneumonia developed in the course of a tertian infection.

Nephritis of severe or moderately severe grade was observed in five cases, but no systematic examinations of the urine could be attempted, so that in the absence of distinct external signs, such as œdema, this lesion might often have been overlooked.

Jaundice was noted in pronounced form in ten cases, most of which were fatal, while a slight jaundice or yellowish discoloration of the skin from this or other causes was seen in the majority of cases of severe malaria.

Anæmia was noted in all the cases examined, and proved to be the most constant of all the symptoms. In the great majority of the active infections, the changes in the blood were those of secondary chlorotic anæmia, but usually without leucocytosis. Usually, even in severe cases, this anæmia was of moderate grade. And it was often a matter of surprise that blood showing so few morphological changes should harbor enormous numbers of parasites. This apparent anomaly was specially evident in negroes. There was always, however, a distinct loss of Hb in the red cells, although the diminution in the number of cells was not always plainly evident in stained specimens. The anæmic character of the malarial blood was almost always apparent as the drop was expressed from the finger and spread on the slide, and in this respect the difference between the malarial and the typhoid specimens was very striking and constant. The condition of the blood was, of course, usually apparent in the faces of the malarial cases; much less frequently in the typhoid cases.

In the severer and more prolonged fevers the changes in the blood became more pronounced, but with the increasing anæmia the number of parasites in the blood became distinctly less. Many of these cases

showed the *early* changes of pernicious anæmia, with extreme reduction of red cells, and poikilocytosis. A few such specimens showed a large number of parasites, which, with this type of anæmia, were usually scarce.

In many prolonged cases the blood showed the changes of secondary pernicious anæmia, with extreme reduction in number and marked variations in size of the red cells, and leucocytosis. It was extremely rare to find any considerable number of parasites in such specimens.

In several chronic cases the changes in the blood were indistinguishable from those of primary pernicious anæmia, megaloeytes with increased Hb constituting a large percentage of all red cells, and megalo-blasts being abundant. These changes had been established within six or eight weeks. Lymphocytosis, relative or absolute, was often observed in these and milder cases, and the eosinophile cells were often distinctly increased.

The evidence derived from the observation of these cases strongly indicates that the anæmia of severe malarial infection progresses for some time after the blood has been freed from parasites, a conclusion that is further borne out by the comparatively large number of deaths (ten) from anæmia and cachexia that occurred in cases showing no parasites in the circulation. The bearing of this fact on prognoses was well illustrated in some of the fatal cases, in which recovery was expected when the blood was cleared of parasites, yet the patients went on to die of progressive anæmia.

No uniform difference could be seen in the progress of the anæmia in the cases of æstivo-autumnal and those of tertian infection. If any existed, it seemed that the tertian infection was more severe in this respect than was the æstivo-autumnal. The anæmia in two fatal tertian cases was exceptionally severe.

The Fatal Cases.—Of six hundred and five cases of malaria, thirty-nine were fatal, at the General Hospital, six and a half per cent.; but it was impossible to estimate the full mortality of the disease, as many patients were transferred to city hospitals during the intervals of improvement.

Of these thirty-nine cases, twenty-five showed æstivo-autumnal infection, two tertian, two double infection with both varieties, and in ten no distinct parasites were found. In the æstivo-autumnal cases, rings alone were found in twelve, crescents alone in nine, and both rings and crescents in four cases. In six of the æstivo-autumnal cases there was dysentery, usually, but not always, amœbic. Four patients suffered from severe diarrhoea with catarrhal colitis. In eight cases there was intense jaundice, and the immediate cause of death in one case was pneumonia, and in another nephritis. The ten patients showing no organisms died from malarial cachexia, or from complications.

(To be concluded.)

POLYPUS OF THE UVULA.

By E. HARRISON GRIFFIN, M.D.,

LECTURER ON DISEASES OF THE NOSE AND THROAT
IN THE NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE;
ATTENDING SURGEON OF THROAT AND NOSE DEPARTMENT
OF BELLEVUE HOSPITAL OUTDOOR POOR, NEW YORK.

THE following interesting case came under my observation this month—interesting on account of its rarity, but more worthy of notice because it emphasizes the fact that an elongated uvula will not give rise to symptoms unless there is also a nasal catarrh at the same time.

If I were asked to name the most common operation on the throat in the hands of the general practitioner, I would say amputation of the whole or a part of the uvula.

On the other hand, if I were asked to name the most uncommon operation in the hands of the nose-and-throat specialist, I would say the amputation of the uvula.

The former traces the tickling in the throat that is such a common symptom of a nasal catarrh to an elongation of the uvula.

The specialist recognizes that the phlegm caused by an obstructive catarrh, whether the obstruction is caused by a deflected septum, the presence of nasal polypi, a hypertrophic condition of the turbinated bone, or an enlargement of the bone itself, lodges in the postnasal space, often covers the pharynx, and produces the tickling in the throat that the general practitioner traces to an elongated uvula.

I have amputated a part of the uvula in only three cases in the space of five years. In this time I have operated in thousands of cases for this symptom—namely, tickling in the throat—by removing some nasal obstruction and establishing nasal breathing.

The tickling in the throat is by this means arrested, and especially so if the patient should have been taught to use his handkerchief properly in wiping his nose, and to stop the habit of hawking.

The patient, a man, native of California, aged forty years, applied with an acute sore throat. An examination showed the patient suffering from follicular amygdalitis. In the examination I noticed the peculiar condition pictured below. The uvula was slightly longer than normal, and at its end was a large polypus. I called the patient's attention to his throat, and asked him how many sore throats he had had in his life.

This was his first. He never had a tickling in his throat, never hawked, and never had had occasion to have his throat treated before. Mr. X. was a very intelligent man and appreciated the purport of all my questions. He used his voice extensively in his busi-

ness, and did not know that he had any abnormal condition in his throat.

Here was a case where the polypus from the uvula almost reached to the epiglottis, and yet failed to produce the tickling, the cause of so many operations upon the uvula.

Suppose this patient had had an acute quinsy following a period of intoxication, an œdema of the uvula in this case would have enlarged it to such an extent that it would have acted as a plug with the swollen tonsils, and would most probably have produced death.

The cause of the polypus in this region is open to question.

Bosworth states, in regard to nasal polypus, that "the most rational explanation of the development of these growths is in the fact that the mucous membrane covering the middle turbinated bone is very soft, of delicate consistence, and is actively concerned in the respiratory function of the nose—viz., serous exosmosis—and as a result of this serous transudation the membrane becomes saturated or water-soaked, as it were, in such a manner as to lead to the development of the peculiar myxomatous condition." He further adds: "As to what peculiar nutritive disturbance in the meshes of the tissue predisposes to this form of degeneration, I have no suggestion to make."

The polypus was removed by an ordinary pair of curved scissors and forceps without any hemorrhage.

The polypus was an inch in length and about half an inch in diameter. This is the first case of polypus of the uvula that has come under my notice.

Papilloma of the uvula is quite common, and bifid uvula an everyday occurrence in the clinic.

112 WEST FORTY-FIFTH STREET.

THE ELECTRIC-ARC BATH.

A CLINICAL REPORT.*

By MARGARET A. CLEAVES, M. D.

THE necessity of the human body for light and air is of such universal recognition that it seems quite unnecessary to refer to it here. Human beings become bloodless and colorless when deprived of sunshine, and an impoverishment of the blood with a diminution of the red corpuscles and the hemoglobin ensues. With it all there is a loss of nerve force and the establishment of profound anæmic conditions.

The value of sun baths has been recognized and practised for ages past both in a desultory and systematic way, and their value is too well established to need comment. In the electric-arc bath there is to be had the most perfect approach to sunlight in existence. The results obtained clinically may be attributed to light,

heat, and ozone, to, in a word, radiant energy, but the combined activities at work are similar to those of sunlight.

It is impossible to supply sunlight to the inhabitants of large cities in proportion to their needs, but by the use of the electric-arc bath this lack can be at least partially combated.

The heat of an arc light is the greatest heat known, and its active horse-power energy is greater than that of the effective sun's rays at the surface of the earth.* The surface of the sun radiates ten thousand horse power per square foot of its surface; the earth receives only a third horse power per square foot, of which about a third is absorbed in the atmosphere, leaving about 0.25 horse power received at the surface of the earth. A good electric arc requires an expenditure of 0.6 horse power. The brightest part of the arc is a small area within the crater of the positive carbon.

The temperature of this brightest part is 6,300° F., and the area of its brightest spot is 0.1 inch square; a stronger current does not make this spot brighter or hotter, it merely makes it larger, and this is the place which radiates most of the energy and is comparable with the sun for brightness. An arc having a crater of one square foot in area would radiate 8,640 horse power, which is nearly the observed amount from the sun; if the crater is taken to be a trifle smaller than 0.1 inch square, say a twelfth of an inch square, then the resulting figure per square foot would be 12,441 horse power, which is in excess of the sun's rate.

During the activity of an arc ozone is constantly produced in greater or less quantities, according to the source of the E. M. F., whether continuous or alternating.

With the alternating current a greater quantity of ozone is generated than with a continuous current arc.

The arc is to be preferred as a therapeutic measure to the incandescent lamp because of the generation of ozone, and also because it gives a spectrum containing in greater quantities all the numerous rays from the deepest red to ultra violet, and especially of the latter.

The healthfulness of the air, especially in the mountains or at the seashore, is due to the great proportion of ozone present.

Ozone has been made the subject of extensive scientific research, and the literature of the subject is both interesting and exhaustive. The scope of this paper does not permit, however, even a brief review of the data thus obtained. It is quite enough here to briefly call attention to the following facts:

Ozone is oxidized in decomposing all substances with which it comes in contact; it is very little soluble in water, coagulates albuminoid matter†, and is almost completely insoluble in this compound. The experi-

* Read at the eighth annual meeting of the American Electro-Therapeutic Association, Buffalo, September 13, 14, and 15, 1898.

• Professor Bullock.

† *Revue internationale d'électrothérapie*, Jan. 6th, 1894, p. 191.

ments of Messieurs Labbe et Oudin go to prove that ozone has an action upon microbes when they are in distilled water, for example, but when in a solid culture medium they are protected by the surrounding substance.

Ozone is dissolved with difficulty in the gelatin water, and that which is dissolved is destroyed in oxidizing the culture medium, thus forming a barrier to its passage into the mass and protecting the subjacent organisms. This they believe is the reason for the varying opinions held as to its antiseptic properties.

The physiological action of ozone is to increase the number of red blood-corpuscles, the hemoglobin, and also the urica, and to establish nutritive changes. There is a difference of opinion as to whether the action of the ozone is a directly physical one or not. In the experiments made by Labbe and Oudin, it was shown that fifteen days elapsed before the red corpuscles were increased.

The value of inhalations of ozone in phthisis and bronchitis, as well as in anæmia and general malnutrition, has been proved beyond question. Dr. Collard,* at the Hôpital des Anglais, noted a marked improvement in the condition of tubercular patients submitted to inhalations of ozone, who were not attacked by hectic fever or purulent auto-infection. M. Labbe and Oudin, as well as others, have obtained the same results. In inhalations of pure ozone from apparatus designed for that purpose an irritation is very apt to be set up within the bronchi, giving rise to an irritative cough, which is sometimes prolonged for hours, and which will, while it lasts, unfavorably influence the appetite and digestion. When administered in too concentrated a form a certain exhaustion supervenes which has been compared by experimenters to that of a person under the influence of chloroform after an operation.

The untoward results which have been noted from the use of inhalations of pure ozone—i. e., hæmoptysis, irritation of bronchial mucous membrane, and impairment of appetite—have not obtained from the action of ozone as generated by the electric arc, or from the convective discharge of an influence machine when diffused in the air of the room, but only when administered in a concentrated form.

Light, objectively, and heat as well,† consist of to-and-fro vibrations of the universal ether, and these vibrations are now universally believed to be of an electro-magnetic nature in their mechanism—that is to say, that the vibrational activity in the ether is both electric and magnetic. It may be that in addition to the other influences at work, there is an action due to this electro-magnetic field. What effect, if any, the metal lining of the bath cabinet may have by reason of its relation to this electro-magnetic field the writer does not know.

There is no doubt but that in man, as well as in plants (evidenced by numerous experiments made upon growing plants), there is obtained an action upon protoplasmic activity by exposure to electric light. Numerous experiments have been made by M. d'Arsonval, Klebs-Löffler, P. A. Khmelevsky, of St. Petersburg, Theodore Geisler, Dr. H. Marshall Ward, of London, and others, which show that both sunlight and electric light have an action upon various bacterial growths. It has been satisfactorily demonstrated in all of these experiments that the inhibitory influence upon the growth of microbes has been from the actinic or chemic rays and that there is no action whatever in the infra red, orange, or yellow region.

Exposure to an electric arc, if exceptionally long, is followed by a condition similar in every respect to that of sunstroke, which has been characterized as an electric sunstroke.

Lavrand* reports the case of an engineer who remained exposed for about an hour at a distance of about three feet to the rays given out by two connected arcs under a current of fifteen ampères. His situation is described as being in that part of the cone of rays where the light was least, but the chemical activity the greatest.

Three hours afterward he felt a tingling in his eyes and soon presented all the symptoms of sunstroke, laceration, redness of the skin of the face, and tingling, and then very severe supra-orbital neuralgia.

The blistering of the skin in the cases treated by the electric arc, as reported by Kozlovski, and also the sunburn following exposure to its influence, are due to the actinic and chemic rays and not to the heat.

For some time it has been regarded as possible to use electric light under such conditions as to make it fairly comparable to sunlight in its power of promoting protoplasmic activity in plants, and the clinical work done thus far substantiates the same for human beings. Whether the form of cabinet used for the electric-arc bath is best for the purpose remains to be seen.

The cabinet used by the writer is six feet long, two feet and a half wide, and seven feet high, built in the corner of one of the office rooms. It is entirely closed in, save for an observation window, which can also be utilized for the admission of fresh air if desired, and is lined with zinc throughout in order to prevent any danger of fire from a fragment of burning carbon. Both ends are fitted up with glass compartments in which are suspended the arc lamps, two in number. These compartments are so arranged that the doors may either be closed or opened. In the latter instance the ozone would be eliminated from the bath. As a matter of fact, they have been used thus far with the doors swung open. The cabinet contains an ordinary wire mattress cot, which is made up as a bed, and upon which the patient reclines. At the New York Electrotherapeutic Clinic

* *Revue internationale d'Électrothérapie*, November, 1893.

† *Electricity in Electrotherapeutics*, Houston and Kennelly.

* *Journal des sciences médicales de Lille*, May 2, 1898. *Presse médicale*, June, 1898.

the lamps are on the Thomson-Houston alternating current mains of a hundred and four volts, and each lamp takes nine amperes at forty-eight volts, the remaining eight volts being consumed in the rheostat.

In the writer's office the current is taken from the Edison incandescent mains of a hundred and twenty volts, and each lamp takes about ten amperes at fifty volts, the remainder being consumed in the rheostat.

Each lamp is provided with a reflector, in order, if indicated by the pathological condition, that the light may be focused on a given part of the body.

It is best that the zinc lining should be painted white in order to facilitate the reflection of light, and as the patient lies at rest in the bath he is bathed in a sea of light equivalent to about four thousand candle power.

The patient is preferably nude, although the applications are sometimes made with only a partial undressing. The eyes are protected by means of colored glasses, and, if desired, the hands may be protected also to avoid any chance of sun burn.

All patients, but especially phthisical and bronchial patients, are directed to breathe in fully and deeply while lying in the bath.

When the same uniform results are secured in a greater number of cases, an effort will be made to rearrange the methods of using and to eliminate certain factors in order to reach more accurate conclusions as to the exact relation between cause and effect.

No definite conclusion has been reached by the writer as to the specific influence at work to produce the changes which have been observed clinically; that ozone plays a large and important part does not, however, admit of question. The influence of a dry climate is also too well known to admit of discussion, and the benefits obtained by a residence in Colorado are believed to be largely due to the dryness of the atmosphere discouraging the growth of bacilli, as well as to the influence of the high altitude in increasing the blood supply to the lungs and improving nutrition.

Experiments have been made showing that an exposure of the *Bacillus tuberculosis* to the action of the solar rays results either in their destruction or diminished vitality. Light is also opposed to their development.

In an electric-arc bath there is an expenditure of energy similar in physical character to an expenditure of energy of the solar rays. It would almost seem that the action which takes place as the result of this expenditure must be a directly oxidizing one; for with the beginning of treatment, even from the first bath, there is a diminution of cough and expectoration.

Nutritive changes manifest themselves later, and may result directly from a stimulus to the pulmonary surface with an increased blood supply to the lung, or later from an increase of red blood corpuscles and hemoglobin in the general circulation.

Patients uniformly present an appearance of being rested and refreshed when subjected to the influence of the electric-arc bath. By its use circulatory changes are established with a uniform regulation of the heart's action, as shown by improved volume and slower rate of pulse; temperature is temporarily augmented; activity of the skin increased; respiration notably improved, fuller and slower, with gradually increasing respiratory capacity; irritability of bronchial mucous membrane promptly lessened, as evidenced by diminution of cough and expectoration.

The stimulus imparted results in a more active dissimulation, as evidenced by increased urea and CO_2 elimination, but is balanced by an equal assimilation, shown by improved nutrition and function.

In an analysis of the cases submitted with this paper it is noted that the establishment of the nutritional change is most marked at about the end of the second week of treatment, which so far as the action of ozone is concerned confirms the observations of Labbe—i. e., that the increase of red blood-corpuscles and hemoglobin is established about the fifteenth day.

In diseases of the respiratory system there has been noted, however, a marked effect from the administration of the first bath upon the cough and expectoration—i. e., a diminution in both. No drugs were given in any of the cases reported, save as mentioned.

After improvement had been established in several cases of phthisis by the action of the electric arc, independent of all other means, the treatment was supplemented by the use of the franklinic current, positive insulation, convective discharge with the crown electrode for from ten to fifteen minutes and with the brush electrode to the entire general surface (nutritional), localized to the chest walls front and back (lungs). The principle involved is the same as in the administration of a cold douche after a hot bath—i. e., to stimulate the electromotive forces of the relaxed skin or tone it up. It is not known that the ultimate results have been bettered by the use of the convective discharge, but as a prolonged exposure to the influence of the arc may be followed by undue relaxation, this has seemed the wisest course to pursue.

The electric arc is being used to some extent in Europe, and was introduced first into France by Imbert de Latouche, of Lyons,* who constructed an arc light cabinet upon the same principle and upon the description furnished him by the writer.

Recently Kochovski,[†] in *Vratch*, has published an account of the treatment of rheumatism and neuralgia by means of exposure to the electric arc. He was induced to make some observation, by the statement of Ewald (medical officer to some linen works), who had noticed that with the introduction of electric weld-

* *Revue internationale d'électricité médicale*, April and May, 1896.

† *Journal des Sciences Médicales*, Vol. 1, No. 1, July 2, 1898.

ing there had been a notable diminution in the number of cases of rheumatism, neuralgia, and migraine, and other nervous disease among the workmen. He attributed it to the beneficial effects of the electric light. Kozlovski at once, in order to bring the electric arc as a therapeutic agent within the reach of his ordinary patients, fitted up his consulting room with a suitable plant and began making his observations. His practice was to place the patient a metre and a half from the light, to protect the eyes with blue spectacles, and also to use a screen of cardboard through which an aperture was cut so as to allow the light to flow upon the affected region of the body. The exposure was from three fourths to two minutes. The patient feels a slight sensation of heat, though the temperature is never raised more than 4° F., where the light falls on the skin. Nothing more is felt until six or eight hours afterward, when itching and tingling are felt and the skin is reddened. Some forty-eight hours later desquamation occurs, which lasts for two or three days. In the course of three months Kozlovski treated thirty-eight patients from thirteen to seventy years of age. There were three cases of sciatica, all of which recovered; four of neuritis, locality not stated, two of which recovered; eighteen of chronic rheumatism, fourteen of which recovered; three of lumbago, all of which recovered; three of occipital neuralgia, of which two recovered; and two of trigeminal neuralgia, one of which was greatly benefited. In most cases three or four sittings produced an amelioration of the pain.

They were continued at intervals of three or four days, according to the amount of cutaneous irritation, but the total number of sittings never exceeded a dozen.

M. Below,* in a recent paper read before the Medical Society of Berlin, reports a hundred and twenty-two patients treated by means of arc and incandescent light baths with sixty-seven cures, thirty-six improvements, and nineteen without results. The best of results were obtained in lupus, ulcers of the legs, muscular rheumatism, and syphilis, while in vascular naevi, pruritus of scrotum and glands, cancer, sarcoma, alopecia, atrophy of optic nerve and cataract, no results were obtained. He attributed the action in syphilis to the profuse perspiration induced and referred to the habit of natives with syphilis, in Hayti and on the coast of Mexico, of covering themselves with sand on the sea beach and exposure to the sunlight while they drink quantities of tea to stimulate perspiration, as exercising a similar influence. In this idea he was not supported by his *compères*, and such curative action as resulted was attributed by them to the heat of the sun's rays, not to perspiration.

M. Below found that a temperature of from 75° to 167° F. is tolerated without disturbance of any sort,

where alarming phenomena present themselves from the use of other methods, and concludes that it is a desirable means of inducing activity of the skin where, because of asthma or cardiac lesions, the usual methods are contraindicated.

The electric arc has been used by the writer in the treatment of anæmia, chorea, eczema, and psoriasis with general malnutrition, but the most extended observations have been made in diseases of the respiratory tract—*i. e.*, subacute bronchitis, bronchial asthma, acute and chronic phthisis.

The cases reported are from the writer's case book, and also from the records of the New York Electrotherapeutic Clinic.

The equipment of both office and clinic is of so varied a nature that other means of treatment have usually been selected for the average case, and therefore the electric arc has not been utilized to a great extent, save in respiratory troubles, and considerable interest has been manifested in its use in this class of cases.

Very many subjects of phthisis find it impossible to leave their homes; their families need them, and, as one patient put it, "to be sent from home is to be deprived of hope and condemned to despair." Therefore everything that offers a chance of improvement without climatic change should be tried.

The writer has no thought that in the electric arc a panacea for this trouble is to be found—far from it; but the uniform results obtained in the series of cases reported suggest its probable value in curative cases. Much more extended observations will be made during the coming year; and the evidence secured, subjective and objective, must speak for itself.

While in an electric-arc bath there are light, ozone, and a dry, hot atmosphere, like that of a midsummer's day, the writer would reiterate that she offers no opinion as to the relation between cause and effect. That is reserved for further study and investigation, in which the physioist must aid the physician.

(To be concluded.)

TYPHOID INFECTION WITH PRIMARY FOCUS IN THE GALL BLADDER.

By ROBERT T. MORRIS, M. D.

FÜTTERER makes a claim for priority in the discovery of the *Bacillus typhi abdominalis* in the gall bladder. His observations on two cases were published in the *Münchener medizinische Wochenschrift*, 1888, No. 19, under the title *Untersuchungen über Typhus Abdominalis*, and he expresses the opinion that relapses of typhoid fever are caused by typhoid bacilli entering the intestine with the bile.

A case which is apparently corroborative of Fütterer's views has recently occurred in my practice. On September 21, 1898, I was called in consultation by Dr. R. E.

* *Revue internationale d'Electrothérapie*, March, April, May, 1898, p. 279.

Doran, of Willard State Hospital, to see Mr. J. L. B., twenty-six years of age, who had been suddenly seized, forty-eight hours previously, with a sharp pain below the right inferior costal margins, which rapidly extended as an acute general peritonitis, with a temperature reaching 102° F., but apparently without accompanying rigors. The patient was constipated until the day on which I arrived. On examination a mass was easily palpated at the site of the gall bladder, and the peritonitis seemed to be most intense at that point. We diagnosed empyema of the gall bladder and operated. The peritoneum was deeply congested and was covered with coagulated lymph in the vicinity of the gall bladder. The gall bladder was distended with a mixture of thin, greenish mucus and thick, tenacious yellow pus. I did not have my culture tubes at hand and no bacteriological examination of the pus was obtained, much to my regret. I drained the wound and the gall bladder with a small wick drain and closed the incision, excepting for the drainage opening. On the evening of the day of operation the temperature rose to 103° F. and dropped on the following morning to 100° F.; pulse, 88; respirations, 24. On the evening of the second day after operation the temperature rose to 106° F. Up to this time the bowels had not moved, but two high enemata of Epsom salts caused a number of loose movements, and the symptoms of dangerously progressive infection subsided rapidly. After this the symptoms of typhoid fever supervened, and the case ran a typical course as one of typhoid fever, ending in recovery in about four weeks, excepting for a small biliary fistula, which was closing spontaneously at last reports from Dr. Doran.

49 WEST THIRTY-SIXTH STREET, December 21, 1898.

INTRAVENOUS SALINE INJECTION IN SEVERE HÆMORRHAGE.

By J. O. COBB, M. D.,

PARMED ASSISTANT SURGEON, U. S. MARINE HOSPITAL SERVICE.

THE following experiments were made for the purpose of demonstrating:

1. The case with which the operation can be performed.
2. The condition of the blood after severe hæmorrhage and injection of saline.
3. The point where it is hopeless to expect favorable results from saline injection.
4. The different temperatures at which the solution may be injected without noticeable harm.
5. The pressure effects of the saline solution on the circulation.
6. The effects of saline injection, while at the same time administering oxygen by inhalation.

It is an easy matter to improvise the apparatus. I took a blowpipe from the post mortem case and boiled it. An ordinary curved medicine dropper would answer the purpose as well. A large bottle was used, and the solution siphoned out with a rubber tube, no precaution being taken to prevent air getting into the circulation nor to prevent infection. An ordinary self-injecting bulb syringe may be used for the injection; or, if one has

an aspirating case, the current of air may be reversed, turning the bottle upside down, and the fluid injected through the needle into the vein.

There are many ways in which the ingenious surgeon could introduce the saline solution. No patient should be allowed to die from the effects of hæmorrhage without at least a trial of saline solution.

Attention is called to the operation as it is usually performed on a patient, if one has the time and is prepared for such an emergency as hæmorrhage.

Thoroughly scrub the arm and prepare the field as carefully as would be done for any operation. If the patient has bled much, it will not be an easy matter to find the veins, as they are collapsed and colorless. Make the incision over the course of the vessels down to the subcutaneous fat and then cut directly across the course of the veins. If there is any trouble in finding the veins in the arm, a large vein can always be found in the leg—the saphenous.

The instruments needed are few. The cannula sold by instrument makers for this purpose is the most convenient. After finding the vein, pass two ligatures around it about an inch apart. Start the fluid through the tube, and then cut into the vein with sharp-pointed scissors between the two ligatures. The solution must be kept running while the cannula is being inserted to prevent the introduction of air. Immediately tie in the cannula, not cutting off the suture; the other is tied and cut off. After the solution is introduced, dissect up about two inches of the vein, put on another suture, and cut out that part of the vein between the two sutures. Any vessel which is graduated, such as a large funnel or bottle, will answer the purpose of holding and marking the amount of solution being introduced.

EXPERIMENT I.—Male dog; weight, thirty-seven pounds and three quarters; hæmoglobin, ninety-five per cent.; red cells, 4,500,000.

July 10th.—Bled from right external jugular until respiration and heart's action ceased. Amount of blood withdrawn, 900 c.c. Saline injected, 1,200 c.c. Temperature of solution, 57° C. In five minutes dog regained his feet and drank water, but would not eat during the day.

11th.—Just twenty-one hours after operation, weight, thirty-seven pounds; hæmoglobin, thirty-two per cent.; red cells, 1,300,000. Hungry and eats well, but does not seem to desire water.

12th.—Same as yesterday, but still weak.

14th.—Doing well, apparently none the worse for the operation. Slight suppurative.

16th.—Hæmoglobin, thirty-nine per cent.; red cells, 2,800,000; weight, thirty-nine pounds and a quarter.

23d.—Hæmoglobin, forty-five per cent.; red cells, 2,800,000; weight, forty-three pounds.

From the first there was a marked leucocytosis, the red cells very pale and smaller than normal.

EXPERIMENT II.—Male dog; weight, forty-three pounds; hæmoglobin, ninety-five per cent.; red cells, 5,000,000.

July 12th.—Bled from both external jugulars, taking 800 c.c. from left side in five minutes and 500 c.c.

from right side in eleven minutes. The veins were widely opened and allowed to bleed without interference. Twelve minutes after bleeding had stopped from vein, opened femoral artery, from which no blood flowed. Nine minutes later dog had ceased any motion whatsoever and seemed to be dead. Two thousand cubic centimetres of saline solution at 48° C. were injected. Dog began to breathe; but, unfortunately, a very large quantity of air was accidentally introduced into the vein before it was discovered. The dog died in a spasm.

EXPERIMENT III.—Male dog; weight, ninety-four pounds; hæmoglobin, ninety-seven per cent.; red cells, 5,000,000.

July 13th.—Bled from right, at same time running saline into left external jugular. After bleeding to the amount of 500 c. c. the blood began to come through, a bright, cherry red, showing that the saline was in the circulation. As the bleeding progressed the blood became thinner and redder. This fluid did not coagulate at all, and what little blood there was in this solution very quickly settled, leaving it clear on top. It had been the intention to bleed this dog to death, but at this point the experiment ceased because the apparatus did not work properly.

Amount of blood withdrawn through the veins, 4,400 c. c. Amount of saline introduced, 3,700 c. c. Temperature of saline, 52° C. The dog was able to move about in a few minutes. Five hours after would not eat, but drank water often. Twenty-four hours after, hæmoglobin, thirty per cent.; red cells, 2,000,000; weight, ninety-one pounds. Eats and drinks well.

16th.—Some oozing into the dressing. Dog doing well. In the evening there was considerable hæmorrhage from the wound on left side. Dog etherized, and bleeding point, a small vein, ligated.

19th.—Hæmoglobin, twenty-two per cent.; red cells, 2,100,000; weight, ninety-three pounds and three quarters. Several tests were made to confirm the percentage of hæmoglobin. The blood count was made with the hæmato-crite, and from some cause probably was not even approximately correct.

21th.—Marked leucocytosis. Red cells are very pale, irregular in shape, and of different sizes.

29th.—Examination of stained specimens of blood showed red cells, irregular, and of different sizes; the smaller and a few of the larger white cells took the tri-acid stain very deeply, while others alongside of them took the stain poorly.

30th.—Hæmoglobin, forty-three per cent.; red cells, 3,300,000; weight, ninety-three pounds. Even at this date there is marked leucocytosis. The dog is apparently in good health; eats well and is playful.

EXPERIMENT IV.—Female dog; hæmoglobin, eighty per cent.; red cells, 4,000,000; weight, thirty-three pounds and a half.

July 15th.—Bled from right external jugular, at same time running saline into left external jugular. The saline was run in much faster than the blood ran out, for the purpose of raising the blood pressure. The right external jugular was ligated on the cardiac side of the wound to prevent regurgitation from the opposite side. The flow of the blood was noticed to rise and fall with raising or lowering the bottle of saline. In all the experiment the flow from the vein could be made to rise or fall by raising or lowering the bottle. Amount of blood withdrawn, 3,000 c. c. Amount of saline introduced, 5,600 c. c. Temperature of saline, 52° C.

Length of time bleeding was carried on, nineteen minutes.

Note.—After withdrawing 800 c. c. of blood, it was noticed that it began to come through much lighter in color and thinner. It shortly ceased to coagulate. The last of the fluid withdrawn was almost pure saline solution, just tinged with blood. It was noticed that the cherry-red coloration ceased shortly before this. I did not know the significance of this fact at the time, but other observations show that in every case, when the cherry or rose color disappeared from the flow entirely, not one dog recovered. Several tubes full of air got into the circulation by accident. I think it made no difference in the result. Respiration gradually got weaker, and ceased in twenty minutes. The pressure of the large excess of fluid in the circulation may have caused the fatal termination.

Necropsy (four hours after death).—Heart and great blood-vessels well distended with fluid colored much like watered port or blackberry wine. There was not a clot in the veins or heart. Lungs collapsed. Veins of mesentery full of air bubbles. Bladder full of urine.

EXPERIMENT V.—Male bulldog; hæmoglobin, eighty-nine per cent.; red cells, 4,700,000; weight, thirty-four pounds.

July 18th.—Bled from right external jugular, at same time injecting saline on the other side. Bleeding continued for ten minutes. Amount of blood withdrawn, 2,650 c. c. Amount of saline introduced, 3,000 c. c. Temperature of solution, 55° C.

Note.—After withdrawing about five hundred cubic centimetres of blood, it began to come through very much brighter. At about 1,800 c. c. the fluid withdrawn was beginning to darken, and in a short while was port-wine color.

Dog died in a spasm while the bleeding was going on. It was noticed that the pressure of the column of saline in the bottle forced the stream through for some time after the dog's heart and breathing had ceased.

EXPERIMENT VI.—Female dog; hæmoglobin, ninety per cent.; red cells, 4,700,000; weight, thirty-four pounds.

July 19th.—Bled from right femoral artery, at same time running saline into left external jugular. Bleeding continued seven minutes and a half.

Amount of blood withdrawn, 1,000 c. c. Amount of saline introduced, 1,800 c. c. Temperature of saline, 54° C. The color of the arterial blood was also modified by the saline being much brighter. In a very short time the solution showed its presence in the blood withdrawn. The last of the fluid withdrawn was nearly pure saline, being hardly perceptibly colored. The dog died in a short spasm, the heart first ceasing to beat.

Note.—The effects from arterial hæmorrhage are more serious than from venous.

Necropsy (immediately after death).—Lungs collapsed. Heart ceased in systole. The fluid in veins cherry red. Bladder full of urine.

EXPERIMENT VII.—Male dog; hæmoglobin, eighty-five per cent.; red cells, 3,800,000; weight, thirty-seven pounds.

July 20th.—Dog thin and not in good health. Bled from right jugular, at same time solution injected into left. In a very short time the color of the blood was modified, but the cherry red soon disappeared, and the fluid came through dark. Amount of blood withdrawn, 1,250 c. c. Amount of saline introduced, 1,675 c. c. Temperature of saline, 48° C. When the operation

ceased the dog was in very bad condition. Lived twenty-five minutes. The heart and respiration became weaker and weaker; the heart ceased to beat several minutes before the gasping respiration entirely ceased.

Note.—Every dog has died when the bleeding has been carried on to the point where fluid has come through dark, like watered port wine.

EXPERIMENT VIII.—Male dog; hæmoglobin, seventy per cent.; red cells, 4,100,000; weight, forty-five pounds and a half.

July 21st.—Bled slowly from left jugular. Heart ceased to beat in five minutes and a half. The heart acted badly from the very first, and the respiration was very jerky, and remained so for hours. When 750 c.c. were withdrawn the dog seemed to be dead, with the exception of an occasional gasp. Amount of blood withdrawn, 750 c.c. Amount of saline injected, 900 c.c. Temperature of saline, 50° C.

Note.—After operation the dog's breathing was very bad. It lay stupid for some time; the respiration was very erratic, and would entirely cease at times. The conjunctivæ were sensitive all the time. Forty-five minutes after the operation the dog got up and walked about for a short time, but was very unsteady. About an hour later had a very severe chill, which lasted for three hours. Drank considerable water.

22d.—Dog very weak, but eats and drinks.

23d.—Hæmoglobin, thirty-four per cent.; red cells, 2,200,000; weight, forty-four pounds; marked leucocytosis. In ten days' time dog back to normal health. The count was up to about 4,000,000, and hæmoglobin, eighty per cent., but the notes were lost, and the statement is from memory.

EXPERIMENT IX.—Male dog; hæmoglobin, seventy-four per cent.; red cells, 4,200,000; weight, thirty-eight pounds and a half.

July 25th.—Bled from right jugular, at the same time running saline into left jugular. Bleeding continued nine minutes. Amount of blood withdrawn, 1,300 c.c. Amount of saline injected, 1,100 c.c. Temperature of saline, 48° C.

Note.—Whenever the respiration became very weak oxygen was given by forcibly distending the lungs with the gas. The method of introducing the gas was by a tube into the trachea after a tracheotomy, the larynx and external wound being closed by a small rubber bag, which was inflated. The method was not altogether satisfactory, as the tube and bag had to be withdrawn to allow expiration. The effect of the oxygen was very pronounced, causing the respiration to become full and strong in a very short time. Five gallons of gas were given, all we had prepared. The dog lived about three hours after the last oxygen had been given and could undoubtedly have been kept alive by constant inhalation of the gas.

EXPERIMENT X.—Male dog; hæmoglobin, eighty per cent.; red cells, 4,500,000; weight, thirty pounds.

July 28th.—Bled from right external jugular until blood ceased to flow. The vein was widely opened to allow rapid bleeding. In three minutes heart beats could not be felt, and bleeding ceased entirely. Respiration jerky and shallow. The amount of blood withdrawn at this time was 600 c.c. Very rapidly seven hundred cubic centimetres of saline solution were introduced, and oxygen was given by means of a bag fastened around the head. It was interesting to observe the dog's very rapid recovery. In less than a minute he was struggling, and in a short time it was necessary to reanesthet-

ize him to be able to proceed with the experiment. As soon as anesthesia was again produced, the left external jugular was opened and 200 c.c. of blood withdrawn. The dog very soon fainted, and the blood began to darken. Oxygen was then given, together with 300 c.c. of saline, at a temperature of 44° C. The oxygen was given for three minutes, at the end of which time the dog was struggling. In five minutes he walked around and was quite lively. It is worthy of note that the effects of a secondary hæmorrhage in this and other cases seem far more serious than those of a primary, and, undoubtedly, the inhalation of oxygen is a necessary adjunct to the saline in saving life after very severe primary or secondary hæmorrhage.

29th.—Hæmoglobin, twenty-seven per cent.; red cells, 1,800,000; weight, twenty-eight pounds and a quarter. Rather weak, but eats and drinks well.

August 3d.—Hæmoglobin, thirty-three per cent.; red cells, 2,200,000; weight, twenty-nine pounds. The dog made a perfect recovery.

EXPERIMENT XI.—Male dog; hæmoglobin, ninety-seven per cent.; red cells, 5,000,000; weight, thirty-four pounds.

July 29th.—Bled slowly from right external jugular. Blood ceased to flow in twelve minutes, 800 c.c. being withdrawn. The heart could not be felt, respiration jerky and weak. Waited ten minutes, then opened the left external jugular, from which there oozed 100 c.c. of blood. The time consumed in obtaining this last blood was ten minutes. With the exception of an occasional diaphragmatic spasm the dog was, to all appearances, dead. The oxygen bag was adjusted and the saline solution started into the vein, and oxygen given by inhalation. The heart began to beat strongly by the time that 500 c.c. were introduced. The respiration and heart's action were fairly good, just one minute from the time the saline and oxygen were started. The dog had regained consciousness before the dressings were applied. Two hours later drank large quantities of water, but ate nothing all day.

30th.—Hæmoglobin, thirty-five per cent.; red cells, 2,500,000; weight, thirty-four pounds. Dog stupid and weak; lies down most of the time. Refuses to eat, drinks water, but refuses milk.

31st.—Dog forced to take milk. Still very weak.

August 1st.—Improved somewhat, but still very weak. Refuses to get up.

2d.—Seems quite sick. Gave Rochelle salts, 450 grains, at once.

4th.—Bowels moved for the first time in six days. Began to eat. Has lost weight; very weak.

5th.—Hæmoglobin, thirty-eight per cent.; red cells, 2,500,000; weight not noted. The dog made a perfect recovery.

EXPERIMENT XII.—Male dog; hæmoglobin, ninety-seven per cent.; red cells, 5,100,000; weight, thirty five pounds and a half.

August 1st.—Bled from right external jugular, and at same time saline run into left. Amount of blood withdrawn, 1,200 c.c. Amount of saline injected, 2,000 c.c. Temperature of saline, 43° C. Oxygen given at same time blood withdrawn. The bleeding was continued about fifteen minutes, and escaping fluid was nearly pure saline. Color bright red throughout. The experiment was not continued because the oxygen gave out. The apparatus was working unsatisfactorily, and several tubes full of air went into the circulation with an audible sound. The dog got up and walked around,

then lay down. An hour and a half later the attendant found the dog dead. It is not known what killed him, or just how he died.

Notes.—It is not necessary to take accurately the temperature of the saline solution, if one is in a hurry.

If the solution feels comfortably warm to the finger, no harm will result from its introduction. The temperature should be about 114° F., but if it is 125° F. do not lose time in cooling it.

It was astonishing that no apparent harm resulted from the introduction of saline solution at the extremely high temperature of 130° F. One would naturally believe that such a temperature would coagulate the albumin and seriously damage the red cells.

Saline given with oxygen will save almost hopeless hæmorrhage cases.

Do not waste time in getting the solution into the circulation.

It is urged that the solution be introduced into a vein, after a severe hæmorrhage, in preference to the slow method of subcutaneous injection.

To furnish as much blood as possible for the purpose of carrying oxygen, bandage tightly the extremities, thus forcing the blood in the capillaries back to the heart. The introduction of small quantities of air into the circulation seems to make no particular difference, for undoubtedly air was introduced into the circulation of all the dogs in these experiments.

All dogs urinated after the pressure had been reinstated by the saline solution. The question of overdistention of the heart must not be ignored by introducing too much saline, for the pulsations became "running" when there was excess of solution. So far as we could tell, the dogs that recovered urinated more frequently, and passed a greater quantity of water than normal, for thirty-six hours after the operation.

Do not let the patient die while the solution is being sterilized. Be prepared for such emergencies; if not, introduce the solution without sterilization, if the case is urgent.

If one does not have time to weigh the salt, take a tablespoonful and toss it into two pints of water.

It is an easy matter to be prepared for an immediate saline injection, for Parke, Davis, & Co. are now preparing sterile normal saline solution, put up in ounce bottles, which, added to the necessary amount of water from the hydrant, kettle, or sterilizer, makes the solution ready for instant use.

The saline solution used was sodium chloride, seven grammes to a thousand cubic centimetres of water.

From these experiments one is led to believe that in opium poisoning it would be advisable to withdraw five hundred cubic centimetres of blood and introduce five hundred cubic centimetres of saline solution.

In the early stages of pneumonia it seems reasonable to believe that the withdrawal of blood, and replacing it with normal saline solution, would relieve the tension of

the pulmonary circulation in the early stages, and would furnish a fluid which would more readily take up oxygen.

The blood count was made with the hæmatocrite, and the hæmoglobin tests were made with von Fleischel's hæmometer. The tests, of course, are only approximately correct.

The blood counts and hæmoglobin tests showed great variations, probably due to the fact that some of the dogs had been kept in the pound until they were sick.

Saline solution and oxygen in uræmic convulsions or threatened eclampsia has already been proved the most efficacious treatment for these terrible complications.

The above experiments were not completed as intended, as I was called to other duties, necessarily interrupting the work. It was the intention to investigate the effects of saline solution in opium poisoning and induced pneumonia in dogs.

I have to acknowledge the very great assistance rendered by Dr. W. W. King, interne, and Mr. E. S. Maguire, hospital steward, United States Marine Hospital, Detroit, Michigan.

DETROIT, September 10, 1898.

Therapeutical Notes.

A Soothing Ointment.—The *Clinica moderna* for November 23d gives the following formula:

R Benzoinated lard	40 parts;
Laudanum	4 "
Chloroform	3 "
Extract of belladonna	2 "
Extract of cicuta	1 part.

M.

Formalin in the Treatment of Hyperidrosis of the Feet.—Gerdeck (*Morgagni*, 1898, No. 41; *Riforma medica*, November 15th) advises painting the feet three times a day with from fifteen to twenty-five drops of formalin.

Urethral Anæsthesia by Rectal Injections.—M. Scharfe (*Gazette hebdomadaire de médecine et de chirurgie*, December 18th) recommends the following:

R Hydrochloride of morphine ...	2½ grains;
Sulphate of atropine	⅓ grain;
Distilled water	750 minims.

M. For external use.

An intrarectal injection of from thirty to sixty drops of this liquid is made to produce insensibility of the posterior urethra.

For Vertical Headache in Women.—According to the *Richmond Journal of Practice* for December, Dr. L. Duncan Bulkley recently stated at the New York Academy of Medicine that experience had taught him the fact, which, however, he could not explain, that full doses of strong nitric acid, five drops three times daily, properly diluted, almost invariably gave complete and prompt relief from that very common complaint of vertical headache and flushings in women.

NEW YORK, SATURDAY, JANUARY 28, 1899.

THE STERILIZATION OF WOMEN.

THE subject of the indications that justify the sterilization of women, with a description of a new procedure for the effecting of that end, forms the subject of an article by Professor P. G. Spinelli in the *Archivio italiano di ginecologia* for October 31, 1898. The question is one of great importance, not only as regards the individual, but also from the standpoint of racial economy.

It is too often assumed that the procreation of children is the sole, or at least the primary, ground of marriage, and there is a strong tendency in the present day to subordinate entirely the rights, emotions, impulses, and passions of the individual to ethnical considerations.

Now, it is beyond doubt that with our present knowledge of the hereditary element in disease, whether physical or psychological, the community has a right to take some measures to protect itself against the reproduction of degenerates, as it has against any other danger that threatens to deteriorate the race. It is such a motive, undoubtedly, that animates the various attempts which from time to time occur to effect legislation prohibiting syphilis, tuberculous subjects, epileptics, etc., from marrying.

Unfortunately, the prohibition of marriage, when all that can reasonably be demanded by the State for its own protection is a prevention of procreation, is the only remedy commonly held out. But marriage, as we have before had occasion to remark, has higher and greater aims than even the procreation of children—viz., the mutual comfort, consolation, and support of two beings of opposite sexes who are, in a rightly assorted marriage, the proper complements of each other, without which union the life of either is, and must necessarily be, incomplete. Neither is the act of sexual congress usually primarily viewed in the mind of man or woman as a means of procreation; but rather as the closest, highest, most intimate embrace and demonstration of love and devotion possible to human nature and dependent for its purity upon its motive. This point of view neither contemplates nor justifies the mere gratification of passion in a physical sense, the experiencing of physical sexual pleasure, for that is the motive of the mere sensualist and debauchee. It is based, rather, on the natural individual instincts that attract one man to one

woman wholly and entirely, in all relations, mental, emotional, and physical.

It is obvious, therefore, that the prohibition of union as a means of protecting the community is a serious wrong to the rights of the individual, upon which the rights of the community are based. We remember to have read a novel, by name *Robert Afterbury*, in which the hero, finding himself tainted with phthisis, desires to break his engagement with the woman he loves, since it would in his eyes be wrong for him either to procreate children or to rob his beloved of the joys and duties of maternity. She, however, discovers that there is insanity in her family, which fact renders it improper for her to procreate her kind, and the pair finally enter into a purely Platonic marriage, which is never physically consummated. She ultimately fills up the measure of her natural cravings by the adoption of an orphan child.

This is, however, a height of self-abnegation which it would be unreasonable to expect many people to attain, and we fear that there are few who, even if they entered upon a life union with such intentions, would be able to keep them.

The chief conditions which, according to Dr. Spinelli, render it for the woman's sake highly undesirable that she should marry, or rather become pregnant, are various cardiopathies, especially where they are associated with phenomena of asystole, however transitory; a phthisical predisposition which, according to Stoltz, may be changed by pregnancy into confirmed disease; persistent albuminuria and chronic nephritis, in which, even if the woman escapes death, the immediate puerperal danger is greatly increased by liability to eclampsia or pernicious anemia; diabetes; chronic anemia, which, under the influence of pregnancy, the author considers, frequently takes on a pernicious character; and a preexisting hereditary mental taint, which is often rendered active by pregnancy, his statistics showing a very grave prognosis in such cases.

From a social point of view the reproduction of degenerates is also a grave question, to say nothing of the social side of procreation by syphilis, tuberculous subjects, epileptics, and neuropathies or those with a mental taint, hereditary or acquired.

To all of these, if any other means of avoiding the dangers, personal or ethnical, can be found, the prohibition of a love union is a harsh and unjustifiable measure, and he says: "It may therefore be affirmed that in cardiopathies, in tuberculous subjects, in albuminuria, chronic nephritis, diabetes, grave anemia, mental maladies, preexistent or developing in the first pregnancy, it is necessary to prevent conception by all the methods"

The process he recommends is a surgical measure and consists in interrupting the utero-ovarian way so as to prevent the spermatozooids from reaching the ovule. Oophorectomy has proved to be often injurious to the entire organism. So-called Malthusian methods often fail; frequently they are merely conducive to immorality, and very often, he holds, they constitute a serious danger to the health of both parties.

The author therefore recommends two methods for the sterilization of women, both of them tolerably easy of execution, and practically devoid of any serious danger. His first method is to open the peritoneal cavity from the posterior vaginal fornix by drawing the uterus downward and forward and making a transverse incision between the utero-sacral ligaments. The tubes are then sought for with the fingers, drawn through the wound, and ligated, unless one or both of the annexa are diseased, in which case they are removed and the suture closed. The operation is slight and the patient able to leave her bed in about twelve days. The second operation consists in opening the anterior fornix between the bladder and uterus; dissecting the bladder away and drawing the fundus uteri through the wound. The tubes are then ligated in two places and divided between the ligatures unless disease renders it necessary to remove one or both of them.

The author has twice practised the latter operation, in the first case in an albuminuric. In this case he ligatured the right tube, and removed the appendages on the left side in consequence of disease. In the second case the patient was cardiopathic with mitral lesion. In neither case was any difficulty encountered, and the result has been permanently satisfactory. At the congress at Turin the author reported an operation by the first method for an uncompensated cardiac trouble with equally excellent results.

Professor Spinelli concludes by saying that while his procedure may have to undergo modification, so far as attaining the best method of securing interruption of the ovario-uterine passage is concerned, it must be admitted that this operative procedure is both easy of execution and does not entail any special danger.

While it is far from our desire to counsel any increase of superabundant surgical enthusiasm, and while we distinctly deprecate any unnecessary "unsexing" of women, we can not but feel that there are numberless instances in which a safe and easy method of rendering women sterile when pregnancy would be a source of more than ordinary danger to the individual, or a direct wrong to the community, is far better than a harsh prohibition of that union without which, when rightly entered upon, the highest aim and incentive of life is in-

complete, and in many cases life itself becomes a burden and a despair.

MINOR PARAGRAPHS.

ACCIDENTAL RUPTURE OF THE SYMPHYSIS PUBIS DURING LABOR.

In the January number of the *Memphis Medical Monthly*, under the heading of An Involuntary Symphysiotomy, Dr. B. F. Turner records a case of *aquabiler justo-minor pelvis* in which traction with the forceps applied at the superior strait resulted in separation of the pubic bones to the distance of about two inches and a half, with a rent of the soft parts extending from the anterior commissure of the vulva into the bladder. This injury was repaired by operation, and, although bony union never took place, the woman was ultimately able to do her household duties without difficulty. Three years after her first confinement, in which a dead child was extracted, she was easily delivered of a living child with the forceps. The pubic bones remain about half an inch apart, and Dr. Turner says: "To-day she runs about as nimbly as any woman, and is, so far as concerns her fitness for childbearing, a better woman than she ever was before."

EXTIRPATION OF THE STOMACH.

M. J.-H. FAURE (*Presse médicale*, December 31st) recently presented to the Paris Surgical Society a woman on whom he had performed, on November 19th, almost total extirpation of the stomach for a neoplasm. After removing the greater part of the stomach he had closed separately the duodenum and the stump of the stomach, and completed the operation by a posterior transmesocolic gastro-enterostomy. The author employed, or attempted to employ, the *écraseur* on the intestinal tunics, which procedure had been lauded by M. Doyen, but he describes the method after trial as detestable. On future occasions he will simply obliterate the lumen of the intestine by means of strong silk sutures drawn tight.

CONGENITAL CHLOROSIS.

JAWORSKI (*Wiener medicinische Presse*, 1897, No. 32; *Centralblatt für Gynäkologie*, January 14th) reports the case of a teacher, twenty-five years old, who at the age of nineteen began to suffer with menorrhagia, emaciation, pallor, loss of appetite, etc. She kept on at her work, however, and did not follow her physician's advice. She finally sought admission into a hospital, but not until she was suffering from such a severe flow that tamponing did not serve to check it, and she soon died. The author is inclined to look upon the case as one of congenital chlorosis of which the profuse menstruation was symptomatic. It is stated, however, that the patient began to menstruate at the age of fourteen, and that menstruation was normal until she was nineteen.

POWDERED TIN AS A REMEDY FOR TAPEWORM.

DOMMES, of Bückeburg (*Allgemeine medicinische Central-Zeitung*; *Wiener medicinische Blätter*, December 29th), seeks to revive the use of tin as a remedy in cases of tapeworm. The metal, he says, should be used in the form of the fine powder obtained by the employ-

ment of galvanism. It is entirely tasteless and does not give rise to toxic phenomena, as male fern, pomegranate, and various other tannicacids sometimes do.

THE CONNECTICUT STATE CAMP.

WE infer from an editorial article in the January number of the *Yale Medical Journal* that the drinking water used in the camp at Xiantic comes from wells situated on the premises, in soil that is probably permeated by refuse matter. Our contemporary rightly maintains that the State ought to supply the camp with water flowing through pipes from some safe source, and not trust to self-purification of the soil in the intervals of the camp's occupation, protracted though they may be.

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 21, 1899:

DISEASES.	Week ending Jan. 14		Week ending Jan. 21.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	17	3	14	4
Scarlet fever.....	161	12	162	17
Cerebro-spinal meningitis.....	0	4	0	5
Measles.....	170	7	159	10
Diphtheria.....	192	30	180	26
Croup.....	21	7	12	9
Tuberculosis.....	203	147	189	176
Small pox.....	0	1	0	0
Chicken-pox.....	45	0	25	0

The Richmond Academy of Medicine and Surgery.—At the last regular meeting, on Tuesday evening, the 24th inst., Dr. A. M. Phelps was to read a paper on Lateral Curvature of the Spine and Pott's Disease.

The Chicago Society of Internal Medicine.—At the joint meeting of the Chicago Medical Society and the Chicago Society of Internal Medicine, on Wednesday evening, the 25th inst., the following papers were to be presented: Acute Articular Rheumatism, by Dr. Henry M. Lyman; The Causation and Symptomatology of Acute Articular Rheumatism, by Dr. Arthur R. Edwards; and Chemical Theories of the Causation of Acute Articular Rheumatism, by J. H. Salisbury.

St. Mary's Hospital, Hoboken.—At the annual meeting of the staff, held on January 16th, officers for the ensuing year were elected as follows: President, Dr. Romeo F. Chabert; secretary, Dr. Charles A. Gilchrist.

The New York Foundling Hospital.—At the last meeting of the medical board the following new members were elected to the board: Attending obstetrician and gynecologist, Dr. John A. Pell; attending physicians, to succeed the late Dr. J. Lewis Smith and the late Dr. Joseph O'Dwyer, Dr. L. Emmett Holt and Dr. Rowland G. Freeman.

Changes of Address.—Dr. Elon N. Carpenter, to No. 110 West Fifty-seventh Street; Dr. F. M. Townsend, to No. 45 West Thirty-second Street; Dr. R. J. Wilson, to No. 279 West Seventy-first Street; Dr. Rudolph Jankowsky, from Crete, Nebraska, to Cedar Rapids, Iowa.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 11 to January 18, 1899:*

ANDREWS, CHARLES H., Acting Assistant Surgeon, is relieved from further duty at Huntsville, Alabama, and will proceed to San Francisco and report to the commanding general to accompany troops on the first transport sailing for Manila.

FOWLER, GEORGE R., Major and Chief Surgeon, is honorably discharged from the military service of the United States.

GORGAS, WILLIAM C., Major and Surgeon, will report to LUBLOW, WILLIAM, Major-General, commanding the Department of Havana, as chief surgeon of that department.

MOSELEY, EDWARD B., Major and Surgeon, and WARE, ISAAC P., Captain and Assistant Surgeon, are detailed as members of the board appointed to meet at the Presidio, San Francisco, for the examination of such officers as may be ordered before it for promotion.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the Week ending January 21, 1899:*

BARBER, G. H., Passed Assistant Surgeon. Detached from the *Glaucier* and ordered to the Naval Academy.

BYRNES, J. C., Surgeon. Ordered to additional duty on board the *Puritan*.

BLACKWELL, E. M., Assistant Surgeon. Detached from the *Vixen* and ordered to the *Franklin*.

GARTON, W. M., Assistant Surgeon. Detached from the *Supply* and ordered to the Washington Navy Yard.

GRIFFITH, S. H., Surgeon. Detached from the *Mayflower* and ordered home to await orders.

HOLCOMB, R. C., Assistant Surgeon. Detached from the Naval Academy and ordered to the Washington Navy Yard.

STOKES, C. F., Passed Assistant Surgeon. Ordered to the Naval Hospital, New York.

WAGGENER, J. R., Surgeon. Orders of January 3d, detaching him from the Mare Island Navy Yard and ordering him to Washington, are amended: ordered to be examined at Washington, and then to proceed home to await orders.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Fourteen Days ending January 19, 1899:*

BANKS, C. E., Surgeon. Detailed to attend meetings of the National Pure Food and Drug Congress at Washington, D. C., January 18 to 21, 1899. January 10, 1899.

KINVOIN, J. J., Passed Assistant Surgeon. Detailed to attend meetings of the National Pure Food and Drug Congress at Washington, D. C., January 18 to 21, 1899. January 10, 1899.

STIMPSON, W. G., Passed Assistant Surgeon. Granted leave of absence for two days. January 12, 1899.

THOMAS, A. R., Assistant Surgeon. Upon being relieved from duty of United States transport *Osage*,

to proceed to Stapleton, Staten Island, N. Y., for duty and as a recruit to quarters. January 6, 1899.

GREEN, J. B., Assistant Surgeon. Detached from duty on United States revenue steamer *Macdonough* and directed to report to medical officer in command,

San Francisco Quarantine, Angel Island, California, for temporary duty. January 12, 1899.

GRUBBS, S. B., Assistant Surgeon. To report at Washington, D. C., for special temporary duty. January 12, 1899.

RODMAN, J. C., Sanitary Inspector. Granted leave of absence for thirty days from January 12, 1899. January 12, 1899.

MCGUIRE, E. S., Hospital Steward. Granted leave of absence for thirty days from February 4, 1899. January 12, 1899.

GOODMAN, F. S., Hospital Steward. Relieved from duty at the Cape Charles Quarantine Station and directed to proceed to Philadelphia, Pennsylvania, and report to AUSTIN, H. W., Surgeon, for duty and assignment to quarters on the barge *Protector*, en route to Havana, Cuba. January 6, 1899.

CARLTON, C. G., Hospital Steward. To proceed to Chicago, Illinois, and report to the medical officer in command of the service for duty and assignment to quarters. January 6, 1899.

SOUTHARD, FRANK A., Hospital Steward. To proceed to Stapleton, Staten Island, N. Y., and report to the medical officer in command of the service for duty and assignment to quarters. January 7, 1899.

PURIFOY, JOHN, JR., Hospital Steward. To proceed to New Orleans, Louisiana, and report to the medical officer in command of the service for duty and assignment to quarters. January 7, 1899.

WERTENBAKER, C. P., Passed Assistant Surgeon. To proceed to Clinton, Ga., for special temporary duty. January 13, 1899.

GARDNER, C. H., Passed Assistant Surgeon. To report at bureau for special temporary duty. January 14, 1899.

Board Convened.

Board convened to meet at the United States Marine Hospital at Chicago, Ill., on Tuesday, February 14, 1899, at ten o'clock A. M., for the examination of candidates for appointment as assistant surgeon in the service. Detail for board: Surgeon HENRY W. SAWTILLE, chairman; Surgeon CHARLES E. BANKS; Passed Assistant Surgeon J. O. COBB, recorder.

Appointments.

GREGORY, GEORGE A., of Maine, to be Acting Assistant Surgeon at Boothbay Harbor, Me. January 11, 1899.

Society Meetings for the Coming Week:

TUESDAY, January 31st: Rome, N. Y., Medical Society; Boston Society of Medical Sciences (private).

WEDNESDAY, February 1st: New York Academy of Medicine (Section in Public Health); Society of Alumni of Bellevue Hospital; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (New Brighton); Penobscot, Maine, County Medical Society (Bangor); Bridgeport, Connecticut, Medical Association.

THURSDAY, February 2d: New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, N. Y.; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington); Medical Society of City Hospital Alumni of St. Louis; Atlanta Society of Medicine.

FRIDAY, February 3d: Practitioners' Society of New York (private); Clinical Society of the New York Post-graduate Medical School and Hospital; Baltimore Clinical Society.

SATURDAY, February 4th: Manhattan Medical and Surgical Society, New York (private); Miller's River, Massachusetts, Medical Society.

Births, Marriages, and Deaths.

Married.

BENNEY—TITUS.—In Brooklyn, on Wednesday, January 18th, Dr. Walter Benney and Miss Alice Livingston Titus.

HOLLISTER—SHELTON.—In New York, on Wednesday, January 18th, Dr. Frederick Kellogg Hollister and Miss Harriet M. Shelton, daughter of Dr. George G. Shelton.

MACADAM—VAN TINE.—In New York, on Thursday, January 19th, Dr. Henry Graham MacAdam and Miss Irene Van Tine.

Died.

CHASTANT.—In New Orleans, on Thursday, January 19th, Dr. Alcee Chastant, in the seventieth year of his age.

HARTMANN.—In St. Louis, on Tuesday, January 10th, Dr. Alexis K. Hartmann, in the sixtieth year of his age.

LYNCH.—In Boston, on Saturday, January 14th, Dr. Samuel Bartlett Lynch, in the thirty-ninth year of his age.

MCGILLICUDDY.—In New York, on Tuesday, January 17th, Dr. Timothy J. McGillicuddy, in the forty-third year of his age.

PEABODY.—In Henniker, New Hampshire, on Tuesday, January 17th, Dr. Leonard Wood Peabody, in the eighty-second year of his age.

READ.—In Tuscaloosa, Alabama, on Friday, January 20th, Dr. John B. Read, in the eightieth year of his age.

WOOD.—In Portland, Maine, on Sunday, January 22d, Dr. William R. Wood, aged eighty-nine years.

Special Articles.

THE LAW IN ITS RELATIONS TO PHYSICIANS.

By ARTHUR N. TAYLOR, LL. B.

III.

THE RIGHT TO PRACTISE MEDICINE AND SURGERY.

(Continued from page 98.)

Judicial Construction of Statutes.—The statutory enactments of the various States have from time to time been construed by the courts of the respective States or of the United States; but these decisions, being usually based upon the particular wording or meaning of the statute in question, are ordinarily of little interest outside of the State in which they are rendered. Some of these decisions, however, either involve a principle of extended application or construe statutes which exist so

generally as to render them of sufficient value to justify an examination.

Constitutional Validity of Medical Acts.—The constitutional validity of the laws prescribing requirements for those practising medicine and surgery has been attacked in nearly every State in the Union upon the general grounds that:

They invade natural rights.

They interfere with vested rights.

They discriminate against persons engaged in the same business or profession, and deny them the equal protection of the law.

Or, they are *ex post facto*.

Our courts, both State and Federal, have, however, almost universally upheld the constitutionality of these acts, conceding them to be invalid only where they contained some specially objectionable feature.

The authority of the legislature to enact a law of the character of those under consideration is included in the police power of the State. The police power is very broad; it has been judicially defined to be that inherent and plenary power in the State which enables it to prohibit all things hurtful to the comfort and welfare of society. It extends to the protection of the lives, limbs, health, comfort, and convenience as well as the property of all persons within the State, and to accomplish this end persons and property are subjected to all kinds of restraints and burdens.*

That the practice of medicine and surgery is a vocation that very nearly concerns the comfort, health, and even life of nearly every person can not be questioned, and therefore a wholesome restraint upon those unprepared to exercise these important functions is clearly the right of the State and its duty as well.

Nearly every State makes special provisions for licensing those who had been engaged in the practice of medicine and surgery in that State for a certain length of time prior to the enactment of the law. The validity of such provisions is attacked on the ground that they create special privileges and allow those who have exercised the right for the prescribed time to continue its exercise without submitting to examination or presenting a diploma; while all who have not practised for such period are obliged to be specially examined as to their qualifications or present diplomas, or both. The answer to this attack is, that if in the wisdom of the legislature the experience gained in practising five or ten years, or any other period fixed upon, within the State is equivalent by way of preparation to the course prescribed for those about to undertake the practice of medicine and surgery, it shall be lawful and will be considered no discrimination to fix these two standards.

It has been observed heretofore that many States extend to non-resident physicians and surgeons the right of being called into the State in consultation, and sometimes the right to extend their practice into the State without being examined or licensed. This has also been attacked as being an unjust discrimination and contrary to the fourteenth amendment of the Federal Constitution. It will be found that such laws do not permit such non-resident physicians to have an office or place for meeting patients within the State, and that they usually impose further restrictions. It therefore can not be said that such non-resident physicians enjoy the same privileges and immunities as a duly licensed resident practitioner.

tioner, and the law is therefore not subject to the objection urged. An Ohio court has upheld the constitutionality of the act, but based its reason for so doing on other grounds. In considering the question, the court said: "We discover nothing unreasonable in the regulations adopted by the statute in question for the admission of persons to the practice of medicine, nor any valid objection to the provision excepting therefrom physicians residents of other States. Physicians called in consultation are usually the most eminent and skillful that can be procured; and those residing on the border of an adjoining State, with a practice extending into this State, can include only those who have a legal standing and established practice in their own State, and which the law regards a sufficient evidence of their capacity and character to admit them to continue their practice here."*

Constitutional Objections to Particular Acts.—Certain features of those acts have at times been found to be objectionable; as, for instance, a law which allowed certain privileges to a particular school of medicine, or which imposed certain burdens upon another school, would be unconstitutional.† A law punishing a duly qualified physician for what is styled "unprofessional conduct" in advertising himself as a specialist in certain diseases would be unconstitutional; for, while such conduct might be contrary to professional ethics, it would in no way be injurious to the public morals or a menace to the general welfare.‡ And so a law requiring all who had not practised four years in one place to procure and pay for a license, but exempted those who had practised for this period from such expense, would be unconstitutional because of the burden imposed upon one class and not upon all.§

But against the main body of the statute law upon the subject, as it stands in the several States, there seems to be no valid constitutional objection which can be urged.

Doctor, Physician, and Surgeon Defined.—"The meaning of the term doctor, or physician and surgeon, as used in the law, is not confined to any particular school or schools, but is considered in the broad sense of one who professes the art of healing. Justice Daly, in a well-considered case, said: "The legal significance of the term doctor is simply a practitioner of physic. The system pursued by the practitioner is immaterial. The law has nothing to do with the merits of particular systems. Their relative merits must become the subject of inquiry when the skill or ability of a practitioner in any given case is to be passed upon as a matter of fact."¶

The supreme court of Wisconsin, thirty years later, following the reasoning of this decision, held that a statute providing for the organization of a county medical society included as well the organization of homoeopaths as of any other school.‡

The question of whether one who "practises bone-setting and reducing sprains, swellings, and contractions of the sinews, by friction and fomentation," is a practitioner of medicine and surgery, was considered in the supreme court of Massachusetts in 1835.§ While such

¶ *Constitution vs. Maritzek*, 1 E. D. Smith, 1.

‡ *Raynor vs. State*, 62 Wis., 589.

§ *Hewitt vs. Chamber*, 16 Pick., 5.

* *Lakeside vs. Rose Hill Cemetery*, 70 Ill., 191. *State vs. Noves*, 4, Me., 189.

a practice does not amount to a general exercise of the functions of the science of either medicine or surgery, it forms an important part of the practice of surgery, and renders the practitioner amenable to the laws affecting the physician and surgeon; also one who gave electric treatment was held to be engaged in the practice of medicine and surgery. The court said: "It is quite unnecessary, we think, that, in order to practise medicine within the meaning of the statute, the practitioner should give internal remedies."* The services of a clairvoyant are within the meaning of the term "medical or surgical services."†

The law of Illinois, in force in 1887, provided that "no person shall practise medicine in any of its departments in this State without the qualifications required by this act." The question arose whether or not this included midwifery. The court was of the opinion that obstetrics was an important department of medicine, and that it was included within the terms of the statute.‡

Moreover, the supreme court of Nebraska, in a well-considered opinion rendered in 1894, held that a Christian Scientist, in the exercise of his practice, came within the statute which provides that any person shall be considered as practising medicine "who shall operate on, profess to heal, or prescribe for, or otherwise treat any physical or mental ailment of another."§

In a more recent case, arising in Rhode Island, the court held that the term "practice of medicine," as used in their statutes, must be understood in the ordinary or popular sense of determining the physical condition of the patient and treating his disease or injury by the ordinary or material remedies, and that it could not be so construed as to include in its meaning the treatment of the Christian Scientist, which takes account neither of physical symptoms and conditions of the patient nor of the application of remedial substances.||

While several of these decisions were based upon the wording of particular statutes, it may be laid down as a general rule that the term doctor, physician, and surgeon, or practitioner of medicine and surgery, as legally used, is broad enough to include all those who profess and practise the art of healing in its several branches.

Decision of Examining Board, when Conclusive.—The authority conferred upon the examining board is usually both ministerial and judicial in its character; by the law of most States the decisions of the board in refusing or in revoking licenses to practise are made subject to review on appeal to the circuit or district court. The law usually provides the manner of taking this appeal, but is sometimes silent upon the subject; this failure, however, to provide for the manner of appealing does not affect the right to appeal. Whenever the law provides that the proceedings of the board may be reviewed upon appeal, it will be necessary for the party who is not satisfied with their decision to bring the matter before the court in the manner provided by the statute;¶ but when the statute makes no provision whatever for an appeal from the decision of the board, his remedy is by

mandamus. A writ of *mandamus* is a command issuing from a court of law in the name of the State directed to some inferior court, officer, or person, requiring him or them to do some particular thing therein specified. In theory, a writ of *mandamus* will issue only to compel the performance of a ministerial act, but will not review any judicial proceeding or interfere with the performance of a function requiring the exercise of judgment and discretion. Should, however, a board refuse to give a candidate a fair examination because of his views regarding any particular school of medicine, or should, when examined, refuse to pass him for a like reason, or refuse to accept his diploma for a similar reason, then *mandamus* would lie; but if, after giving him a fair examination, they determine that his knowledge of medicine is not sufficient to entitle him to practise, or if, after hearing evidence against a legally qualified practitioner in the manner provided by law, they decide he has been guilty of an offense justifying the revocation of his certificate or license, such decisions are not subject to review under a writ of *mandamus*. In New Jersey the board has refused to register the applicant on the ground that his diploma was not issued by a reputable school or college of medicine and surgery. Under a writ of *mandamus* the court refused to consider the evidence as to whether the judgment of the board was correct, because the board had acted in a judicial capacity in arriving at this conclusion.*

In Missouri the supreme court, in considering practically the same facts, rendered the same decision; the judge, however, in delivering the opinion, said: "It is thought best to say this in conclusion, that, notwithstanding what has been said relative to the discretionary powers of the board of health, that [*sic*] according to the express terms of the provision in section 2, such discretionary power does not extend to discriminating against any particular school or system of medicine, and that, should such discrimination ever occur, the limits of discretionary power will have been passed."†

Summing up, it may be stated generally that the action of the examining board is not final. If the statute gives the right of appeal, the court having jurisdiction will review the proceedings of the board, and by its judgment rectify errors, should any be found. And the right to review the grounds of refusal on appeal is not confined to cases of refusal for unprofessional and dishonorable conduct, but, where the statute provides for appeal in "all cases of the refusal of a certificate," the court may examine, or direct the examination, of a candidate as to his competency.‡ Where no right of appeal is given by statute, a writ of *mandamus* will lie to compel the board to do those things which the law makes it their duty to do, and even to rectify a manifest injustice resulting from an abuse of their discretionary powers.§

Illustrations.—It will be observed from the foregoing that it is the purpose of the law to guard against arbitrary and unjust or unfair conduct on the part of the examining board. A case once arose in New Hampshire which very aptly illustrates this. A candidate applied to the board for a license to practise medicine, surgery, and

midwifery; he produced a diploma which fulfilled the requirements of the law, but the board refused to grant the license on the ground that he was not worthy of public confidence. The board has the power under the law of New Hampshire, "upon due notice and hearing, to revoke any license granted by it, when improperly obtained, or when the holder has, by conviction of crime or for other cause, ceased to be worthy of public confidence." The court held that the board had no right to refuse the applicant a license solely upon the ground that he was "not worthy of public confidence," without first giving him due notice and a fair hearing. If then facts were fairly proved by evidence adduced showing him to be unworthy of public confidence, the license would be properly refused.*

And so, when the board established a rule that every medical college should by a certain date furnish the board with a list of its matriculates and the basis of their matriculation, and in the event that any college failed to comply with this request it should not be considered "in good standing," the court held that this rule could not be enforced against an applicant who had graduated from a college in good standing which had not complied with the rule, if it was shown that the college had no notice of the rule until after the date fixed.†

Letters to the Editor.

THE GENELLA FORCEPS.

NEW ORLEANS, January 15, 1899.

To the Editor of the *New York Medical Journal*:

SIR: Referring to the letter published by Dr. Ernest Laplace in your issue of January 14th, I have the honor to agree with him in his statement that his forceps is not a modification of Dr. Murphy's. The only answer necessary to the rest of his letter is that my article has been in the possession of the *New York Medical Journal* since July 29th, and consequently had been written some months previous; therefore I could not have taken any of my information from any source published since that date.

If the Genella forceps has anything about it that unfits it for the operation it was intended for, I have not yet found it out, although I have studied the subject very carefully. LOUIS J. GENELLA, M. D.

THE NEW YORK BOARD OF HEALTH'S SERUM BUSINESS.

187 SECOND AVENUE, NEW YORK, January 17, 1899.

To the Editor of the *New York Medical Journal*:

SIR: I mark with interest the letter from Dr. George W. Cox, of Chicago, on the specification of the New York municipal antistreptococci serum in the report of the American Gynecological Society, published in your issue of January 14th.

Dr. Cox in his valuable letter comments on the difficulty of understanding why this discrimination against other makers should have been made by the society's reporters, and cites the undisputed fact that high medi-

cal authority has already scored the New York board of health and its bacteriological laboratory for engaging in a commercial venture which does not come within its proper province.

Not only is every word of this true as regards the particular serum which elicited this expression of opinion, but it is true in other directions as well. Much might be argued against the conduct of the bacteriological laboratory on the score of false and perverted municipal economy in thus engaging in competition with commercial interests, a competition which in the very essence of existing social conditions must be destructive. Postponing that branch of the discussion, I wish to call attention to a minor detail barely touched on by Dr. Cox.

Your learned correspondent from Chicago writes: "The serum's reputation as a 'standard' product depends very largely upon what the New York board of health says about it." The same is true of all the board's serum products. It alleges high potency for all its serums, but the claim is supported by no authority higher than its own test of that which it has made. A commercial manufacturer must get a report of his serum product from some independent authority, who is not himself a competing manufacturer, before he can gain professional attention. The municipal body may say what it pleases about the wares it has for sale, and put its advertising matter forward as scientific pronouncement of attested worth. If this is as stated by Dr. Cox there must be some misconception somewhere. When, in January last, the State board of health appointed Dr. Dillon Brown and Dr. W. H. M. May a committee to fix upon a method of testing serums which might be offered for use in practice in this State, Dr. George E. Fowler communicated the information to the commercial manufacturers of serums. With commendable unanimity the commercial laboratories agreed to submit their products to independent competitive test without hesitation. The reason why the project fell through is said by bacteriologists to be that the board of health stated that, so long as the methods of test were as uncertain as they then were, no good results could be reached.

There can be no objection to the manufacture of serum by the bacteriological laboratory of the New York city board of health for purposes of bringing relief to the sick poor. That seems legitimate on the part of the city, and a free interpretation would be allowed as to what should constitute a gratuitous system under the cloak of charity. But when the city goes beyond this generously established limit and enters the market as a competing manufacturer and vendor of its product it may well be that opposition should be developed which might confound that which is legitimately a municipal charity with that which is purely commercial. It is suggested that the city can not be too careful to keep the two functions rigidly distinct. If they had been successful hitherto in so doing they would not have encountered such criticism as that in the letter which has served as a text for this communication.

LOUIS FISCHER, M. D.

PER OS AND "PER ORIM"

Boston, January 18, 1899.

To the Editor of the *New York Medical Journal*:

SIR: I have read with much interest your reply to a criticism, by one of your readers, of your use of the

* *Gage vs. Conners*, 63 N. H., 92.

† *State ex rel Johnson vs. Lutz*, 136 Mo., 633, 38 S. W. Rep., 471.

word *os* in the phrase "*per os*," instead of "*per orem*," as meaning "by the mouth," in which you claim that your version is the correct one. I am somewhat impatient at his delay in replying to your criticism, and venture to call your attention to a good Latin authority, *Harper's Latin-English Lexicon*, published in your good city. If you turn to the word "*os*" you will read as follows: 1. "*Os, oris*, the mouth." After a series of etymological paragraphs, if you turn the leaf you will find: 2. *Os, ossis*, a bone, plural *ossa*. So there are two Latin words *os*; and when you write the phrase *per os*, as signifying by mouth, you use the accusative singular of the second *os*, and the meaning would be "by the bone."

I regret to see how general the use of *per os* is getting to be in the medical journals south and west of New England. I have a very vivid recollection of the two words *os*, and the distinction between them, since my schoolboy days.

Boston.

P. S.—I have never yet met the phrase "*per os*" in any of the English, Scotch, or Irish medical journals which I read.

* * We have held back "Boston's" letter from the printer for several days, in the hope that he might fall in with some schoolmaster—one qualified to teach Latin "south and west of New England" would do—and would in consequence send us a request to suppress his communication. But he seems to persist in the error of his ways. We have, indeed, received a second letter from him, but it only goes to enforce his contention that there are two Latin words *os*. As that fact has been known "south and west of New England," to say nothing of the rest of the world, from the remotest scholastic period, there is no good reason for our printing "Boston's" second letter. What he says is not to the point, and "*per orem*" is nonsense. "Boston" admits that he is impatient. Now, impatience is not conducive to success in controversy. It leads one to overlook little things. We presume that in this instance it has led "Boston" to overlook the fact that both the words *os* are neuter, and therefore in both instances the accusative is the same as the nominative.

Proceedings of Societies.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Meeting of November 2, 1898.

The President, Dr. S. ALEXANDER, in the Chair.

Report of a Case of Stillbirth due to Syphilis, in which Both Parents contracted the Disease after Conception.—Dr. WINFIELD AYRES presented this report. He said that many cases had been recorded of syphilitic children having been born to a mother who had contracted the disease after conception. Chancre, developing in the mother at any period between the time of conception and the eighth month, might be followed by a syphilitic child, but he had not been able to find the record of a case of stillbirth with the history that both parents had contracted syphilis after conception. In the case to be reported the father had developed chancre two months, and the mother four months, after impregnation.

The history of the case was as follows: On July 14, 1897, Mr. F. had called him to see his wife. Both he and she were suffering from syphilis. He had developed a chancre seven, and she five, months previously. The wife was suffering from mucous patches in the mouth and throat, with afternoon headaches and pains in the tibiae. Mr. F. said that after he had been treated for his chancre three weeks his doctor had told him that he could safely have connection with his wife, though the sore had not completely healed. His wife had developed a chancre just four weeks after this connection.

When the speaker had first seen her she was at full term. She had been taking medicine for about two months without obtaining any relief from her symptoms. The fœtus was apparently healthy, as vigorous movements could be felt, and the fetal heart could be distinctly heard. She was given a thirty-second of a grain of the biniodide of mercury, and five grains of the iodide of potassium, three times daily, and her husband was ordered to take of the same drugs a twelfth of a grain and ten grains respectively. By mistake, the wife took a tablespoonful of her husband's medicine three times a day for three days, or, at each dose, a third of a grain of the biniodide and sixty grains of the iodide of potassium. She became intensely salivated; the gums and tongue swelled badly, and she suffered from severe pains in the lower jaw. Simultaneously with the pain in the jaw she ceased to feel any movement of the child. Her labor pains began on the 23d, at 8 p. m., and continued with moderate severity until 11 a. m. of the following day, when he was called. The *os* dilated to the size of the proverbial silver dollar, and the child was born two hours and a half later, the labor being perfectly normal. The child was macerated, and had the appearance of having been dead for several days. There were no marks of syphilis about it. There was no probability of a previous syphilis in either of the parents, as there were no marks of the disease on them, and they had had four perfectly healthy children. Both also denied a previous syphilis.

Dr. Ayres said that the question might be raised: Was not mercury, rather than syphilis, the cause of the stillbirth? In his opinion it was simply a coincidence. The fact that the child had no indication of syphilis about it proved nothing conclusively, because many children were born looking perfectly healthy, in whom hereditary syphilis developed later; moreover, in most stillbirths due to syphilis the fœtus died, as this one did, during the last few days of gestation. Mrs. F. gave birth to a syphilitic child on September 5, 1898. She had been under constant antisyphilitic treatment since the stillbirth, and had shown no signs of the disease.

Report of an Encapsulated Stone in the Prostate, with the Presentation of Specimen.—Dr. AYRES also made this report. He said that encapsulated stone of the bladder was not so very uncommon, but the method for removing the calculus employed in this case seemed to him unique. The history of the case was as follows: F. C., aged twenty-seven years, a physician by occupation, came to see him last June. Five years ago he had had a severe attack of pain in the right inguinal and lumbar region, with pain in the testicle, lasting two or three hours. Three years ago he had had several similar attacks which he had attributed to renal colic. After these, he thought he had passed several stones, because he had heard sounds, as of small, hard substances, striking against the sides of a tin pail which

he was using for a urinal, but he had not examined the contents to see if he was correct. One year ago he had had an attack of pain over "McBurney's point": the appendix had been removed and found to be catarrhal. After the operation he had been relieved of pain. He had had painful urination for the last two or three years. At times the stream would stop suddenly before the bladder was emptied, while at other times it would be perfectly free. He had passed some blood-corpuses, but no blood clots. On coming under observation there had been great difficulty in urinating for about six weeks previously. The stream was very small. The act of urination usually required about five minutes, and was accompanied by severe pain in the head of the penis and testicle, and sometimes by shooting pains in the leg. The urine, for the most part, was clear, though occasionally it contained a mucous cloud, with a few pus and blood cells. He had examined him for stone thoroughly, but had failed to find one; yet as the searcher passed through the prostate there had been just one rub, as though it were passing over an imbedded stone. Rectal examination had revealed a small, hard mass in the left lobe of the prostate, apparently situated more in the superior than in the inferior portion. It could not be dislodged. When seen again, three days later, his symptoms had been very much aggravated, but still the mass could not be dislodged. When next seen, seven days later, he said that he had been much more comfortable until the preceding day, when he had had to urinate every fifteen minutes. The stream was small and urination caused great pain. On again manipulating the prostate, it was found that there was considerable softening on the left side, around the original point of hardness. After the manipulation he urinated, and, with the first gush of water (which had been hard to start), he passed the stone. There was also considerable pus in the urine. He had had no return of his symptoms since the stone was passed.

From the fact that no stone could be detected in the bladder by the searcher, and that the hardness felt through the rectum was always in the left lobe of the prostate, the diagnosis of encapsulated stone of the prostate was unquestionable. The capsule was in such a position as to obstruct the outward flow of urine, though it allowed a large catheter to pass readily.

The patient had been repeatedly examined for stone by prominent surgeons, all of whom had failed to find one. One surgeon had also obtained a slight rub, but, failing to repeat it, he concluded that there was no stone.

Dr. Ayres said that he believed he had set up an inflammation of the capsule of the stone by his repeated manipulations, and had at last ruptured the capsule, which had been weakened by the inflammation, thus freeing the stone. The size of the calculus was six by eight by thirteen millimetres, and it was twenty three millimetres in circumference in its smallest diameter. The stone was passed with very little difficulty, probably owing to the fact that the patient had frequently had large sounds passed upon him before this.

The case was apparently one of renal calculus, originally, the calculus having descended and become caught in the dilated prostatic urethra.

Prostatic Enlargement and Vesical Calculi; Suprapubic Cystotomy, and Prostatectomy by Alexander's Method.—Dr. PARKER SYMS reported the following case and exhibited the specimen:

A Hungarian shoemaker, sixty-six years of age, was

admitted to Lebanon Hospital July 15, 1897. He gave a history of having begun to have pain in the region of the bladder, with frequent and painful micturition, about nine months before he was admitted to the hospital. His symptoms had steadily increased in severity, and, at the time of admission, the patient was a good deal of a sufferer. He had the characteristic symptoms of obstruction to the urinary flow, and his urine showed some albumin. It was alkaline in reaction, and contained mucus and pus, but no casts were found, and no blood. The patient's general condition was very fair for one of that age. Examination showed a decided but not excessive enlargement of the prostate, especially marked in the left lateral lobe. Intravesical examination showed the presence of calculi. There was also residual urine amounting to over an ounce. On July 21st, under other narcosis, suprapubic cystotomy was done, and five calculi of irregular shape, and about half an inch in diameter, were removed.

Further exploration of the bladder and prostate at this time determined the operator to enucleate the prostate through the perineum at once. Accordingly, a perineal incision was made, the membranous urethra was opened according to Alexander's method, and, with two fingers of the left hand in the bladder, pushing down the prostate into the perineum, enucleation of the lateral lobes was accomplished with great ease. There was no marked middle lobe, but the lateral lobes were crowded quite close together, and decidedly encroached on the urethra. The entire operation, including the cleansing, etc., consumed fifty-five minutes. After the operation the bladder was drained both suprapubically and by a perineal tube. The treatment consisted in frequent washings and the ordinary care required for patients in this condition. The patient made a steady recovery, which was, however, somewhat delayed owing to the fact that slight suppuration occurred in the fascia around the suprapubic wound. This was not sufficient to cause severe constitutional symptoms, but retarded the healing. The perineal wound healed promptly after the tube had been removed. The suprapubic wound closed in about six weeks. When last observed, which was in October, 1897, or about nine weeks after the operation, the patient had complete control of his bladder, the cystitis had been practically cured, his urination was painless and normal as to frequency, and there was no residual urine.

Complete Ablation of the Breast for Carcinoma.—Dr. SYMS reported this case, and exhibited the patient to show the excellent functional condition of the arm. The patient, Ellen E., single, aged sixty years, had been admitted to the New York Cancer Hospital on February 7, 1898. She had begun to have pain in the right breast two years and a half before, and, after six months, had noticed a small lump in the lower part of the right breast. Since then she had had lancinating pains in the breast, and the lump had steadily increased in size. In June, 1897, this lump had softened and broken down, and ever since then there had been a free discharge. She was markedly cachectic, very much emaciated, and debilitated, owing to the constant discharge from the tumor of blood and detritus, and undoubtedly was suffering from a low grade of septicaemia. Her heart action and general condition were so poor that it was at first thought to be impossible for her to stand any prolonged operation, and that the disease was so far advanced that nothing but a palliative result could be expected from the ablation. However, ten days of active

treatment by tonics and forced feeding, with the patient resting in bed, greatly improved her condition, so that she appeared to be able to undergo an operation. The right breast was generally enlarged, and at its lower and outer part was a characteristic, sloughing carcinoma, having a very foul-smelling base. The operation was done on February 18th. The sloughing area of tumor was first thoroughly disinfected with Paquelin's cautery, then a wide incision was made, encircling the breast and extending up along the outer border of the pectoralis muscle toward the axilla, and a second incision was made from the outer half of clavicle, connecting with the first incision nearly at a right angle. The pectoralis major and minor muscles, the subclavicular fat and glands, the axillary fat and glands, and the breast with the tumor were removed in one mass. As the ablation was made from above downward, the vessels were cut but once, and the operation was, comparatively speaking, a bloodless one.

Undoubtedly, owing to the patient's enfeebled condition, the surface that necessarily had to be left to granulate healed rather slowly, but her general condition steadily improved, so that at the present writing she was in excellent health. She now had no evidence of a recurrence of the growth unless there were some under the scab covering the site of latest cicatrization. The function of the arm was particularly good. She could move it with strength in all normal directions, and without the slightest limitation or restriction.

Dr. ALEXANDER said that the case of prostatectomy was a favorable one for good results. He was pleased to learn that others were adopting his method. He had found that in thin subjects it was perfectly possible to perform enucleation without making a suprapubic opening at all, simply by pressing down behind the pubes.

Dr. A. B. JOHNSON said that one would suppose that these complete operations for carcinoma of the breast had obtained a sufficient reputation to make it the duty of every surgeon, called upon to operate upon such cases early, to do the most complete operation possible, yet it was only a few days ago that a prominent surgeon in this city had expressed the opinion that these extensive operations were needless and no more efficacious than simple excision of the tumor. The speaker said that this case, and many others that he had seen, seemed to prove beyond all peradventure that a large proportion of the patients, if operated upon in this way sufficiently early, were really cured. Any one familiar with the miseries consequent upon the incomplete operation would never wish to do it or see it done. He had recently operated upon a lady who had been subjected to five operations for recurrent carcinoma of the breast and cervical glands. If the glands were already involved, one must expect a recurrence. If this woman had been operated upon properly at first she would probably have been well to-day, because she had stood these numerous operations exceedingly well and had maintained a fair state of health. The original operation had merely removed the tumor.

Dr. SYMS explained that he did not present this patient as illustrating the best results of this operation. The disease had clearly existed over two years in her case, and consequently it was almost certain that there would be a recurrence. His object in presenting her was to show the excellent preservation of the function of the arm. This complete operation, being done almost entirely by blunt dissection, was almost bloodless; the important blood-vessels were secured before being cut,

and the effect on the patient was less severe than that of an incomplete operation. This woman had been able to pursue her occupation of washerwoman in spite of the extensive operation done.

Sarcoma of the Ovary with Ovariectomy, and Sarcoma of the Kidney with Nephrectomy, Both in the Same Case.—Dr. C. C. BARROWS reported this case. The patient, a woman of fifty-eight years, had come under his care early in April because of a tumor which she had discovered in the right iliac fossa. The operation showed the presence of a sarcoma of the ovary, and this was removed. She recovered promptly, but returned three months later with a tumor in the region of the kidney. Through the anterior incision this tumor was removed, and proved to be a sarcomatous kidney. He felt confident that this second growth had not existed at the time of the first examination. Both of the tumors had been examined by a pathologist, who reported them to be sarcoma.

A Vermiform Appendix containing a Minute Piece of Bone.—Dr. CHARLES PHELPS reported this case. He stated that the attack had begun eight days ago, but the patient had not come under his observation until three days ago, and had been operated upon to-day. A small abscess had been found and evacuated. A perfectly smooth mass, feeling like a kidney, had been brought into the wound, and had been found to contain the appendix. Within this appendix was a minute piece of bone. The irritation produced by this foreign body had resulted in the production of this mass of inflammatory exudate. Some surgeons, he said, maintained that they had never found a foreign body in their cases of appendicitis; he had found them quite frequently, but this was the most minute one that he had met with.

Dr. ROBERT T. MORRIS said that usually the things which were called grape seeds, etc., proved, on searching microscopical and chemical examination, to be ordinary concretions of insoluble salts, mixed, in most cases, with more or less fecal matter. For this reason one should be careful in determining this point. He had found a piece of apple core in one appendix, and it was the only foreign body that he had discovered in his cases. In one of Dr. Wyeth's cases he had seen some lemon seeds.

Memorial of the Late Dr. George McCreery, Major and Surgeon, United States Army.—Dr. N. S. JARVIS presented this memorial on behalf of the committee appointed for that purpose, and said that it was his sad duty to pay this last tribute to their late associate, Dr. George McCreery, Surgeon, United States Army, who died on August 26th, while *en route* to home and loved ones, having survived all the dangers of battle and all the horrors of pestilence at Santiago.

He regretted that more eloquent lips or skillful pen had not been selected to present this memorial, for his was an unusual instance of that fearless, self-sacrificing devotion to duty, that patient courage which marked the loyal physician, the brave soldier.

Dr. McCreery was born in New York in 1854, his early education having been acquired at St. John's College, Fordham, where he received the degree of A. B. in 1874, that of M. A. in 1876; his medical degree was obtained in 1877 from the Bellevue Hospital Medical College, and shortly afterward he entered the hospital as a junior on the Second Surgical Division. After the completion of his tour as house surgeon, he was commissioned in the United States Army as an assistant surgeon, passing through the various grades to his majority, which he reached a short time before his untimely death.

Dr. McCreery's military service was performed mostly on the Western frontier, his first assignment taking him to the Department of Arizona, in those days the most dangerous and exciting section of the far West. While post surgeon at Fort Apache in the White Mountains of Arizona he accompanied the command of General Eugene Carr into the heart of the hostile White Mountain Apache stronghold, then led by the notorious Pedro. The troops were attacked about forty miles from Fort Apache and were compelled to contest every step to the post. One of the troop commanders was killed, and many enlisted men were killed or wounded. The post itself was attacked, and the garrison, containing many women and children, were saved by the timely arrival of Carr's command. To pick up and succor wounded men in the face of constant fire from an enemy that acknowledged no obligation to the helpless called for no small amount of personal courage and coolness; but with the true instinct of the brave man and faithful physician Dr. McCreery unflinchingly performed his whole duty. General Carr, who commanded these troops, related to me the circumstances of this our associate's baptism of fire. Dr. McCreery was again under fire in a skirmish with these Indians two days later; he afterward performed extensive field service in the many expeditions in this and subsequent years, being transferred to Dakota in 1883.

At the outbreak of the present war, being assigned as surgeon to the Sixth United States Cavalry commanded by Colonel, now Major-General, Samuel Sumner, he accompanied the regiment from Tampa to Cuba, and was present in the attack on the Spanish defenses at San Juan hill, where he again evidenced that courage which had marked his entire army career. The demand for surgeons at the base became so great that Dr. McCreery was detached from the Sixth Cavalry and assigned to the division hospital, and finally placed in command of the yellow-fever hospital at Siboney. Here he fell a victim to that dread disease and, by a strange coincidence, was relieved by Dr. W. C. Gorgas, United States Army, who had been Dr. McCreery's junior assistant at Bellevue.

While convalescing from yellow fever, our associate was attacked by dysentery; in his exhausted state he left Santiago on a transport on August 15th, but gradually sank, and on the 26th of August, almost in sight of his home, quietly passed away.

As a physician, Dr. McCreery was skillful, thoughtful, and studious, and his many deeds of kindness and thoughtful consideration for the sick and suffering had endeared his memory to his comrades. As a man, he was punctilious, straightforward, and honorable in all things.

Surely, said the speaker, our venerable Bellevue had made many sacrifices to our national glory, our country's defense.

HEADQUARTERS, DEPARTMENT OF TEXAS,
SAN ANTONIO, TEXAS, April 11, 1899.

Brigadier-General Charles Sutherland, Surgeon-General, United States Army, Washington, D. C.

MY DEAR GENERAL: I see by Washington press dispatches, though nothing official has yet reached me, that Captain George McCreery of your department will soon leave Fort McIntosh, Texas, and be ordered to duty in the Department of the Platte at Fort Sully, Nebraska. I can not allow so accomplished a medical officer to leave the Department of Texas without a personal note to you my regret that we must lose his services, though

I feel that he is entitled, after a long tour at one of the most trying of our Rio Grande stations, to a change of climate.

I recently inspected Fort McIntosh, including its admirable hospital, and send you this unsolicited testimony to the exceptional efficiency and ability of Surgeon George McCreery, whose professional and social standing in this department has earned for him my highest respect and warm personal regard.

Yours faithfully,

[Signed.]

FRANK WHEATON,

Brigadier and Brevet Major-General, United States Army.

THE ARMY AND NAVY CLUB, FARRAGUT SQUARE,
WASHINGTON, D. C., February 19, 1895.

Brigadier-General O. B. Willcox, United States Army, Retired:

GENERAL: Referring to letter of Colonel H. C. Cordin, assistant adjutant-general, dated Headquarters of the Army, July 7, 1894, referring to my recommendation when colonel of the Sixth Cavalry, dated Fort Wingate, April 24, 1890, that First-Lieutenant George McCreery, assistant surgeon, be brevetted captain for gallant service in action against hostile Apache Indians at Cibien Creek, Arizona, August 31, 1881, and major, for gallant service in action against hostile Apache Indians in their attack upon Fort Apache, Arizona, September 1, 1881, and requesting you, if you so desire, to submit your recommendation as late department commander, with a specific recital of the details connected with an act or acts of gallantry on this officer's part during the engagements referred to; which paper you referred to me by indorsement dated January 21, 1895.

I have the honor to state, after refreshing my memory by inquiries from officers and others, as follows:

On the afternoon of August 30 (not 31st), 1881, in the action against hostile Apache Indians at Cibien Creek, Arizona, after Captain Hintig had fallen I requested First-Lieutenant and Assistant-Surgeon George McCreery to see him. He went without hesitation, although the enemy's bullets were raising puffs of dust about Hintig's body, and, after ascertaining that he was dead, he proceeded to gather up the wounded, particularly Private Bird, or Byrd, of Troop D, Sixth Cavalry, who had been wounded trying to save his captain, and who, with others, was lying where the bullets were striking.

On the morning of August 31, 1881, while on the march from Cibien to Fort Apache, Arizona, First-Lieutenant and Assistant-Surgeon George McCreery had charge of a desperately wounded soldier named Foran, of Troop D, Sixth Cavalry, who was shot through the bowels, and who, being carried along on a horse, had to be supported, but nevertheless frequently threw himself off during the night march from the pain. This caused Dr. McCreery and the two or three men with him to fall behind till they were over half an hour in rear of the column, and the danger was considered imminent; but Dr. McCreery remained with the patient till he died on the Maricopa range of mountains, when his body was tied across the horse and brought forward more rapidly.

These two acts of gallantry, or rather the first of gallantry and the latter of devotion, are of the nature of supported men in duress, and need no comment, in my opinion, on the doctor or the character of action and man.

I can not recall the details of acts of Lieutenant

McCreery during the attack on Fort Apache, which occurred September 1, 1881, except that he had charge of his hospital, which was on one of the exposed sides of the post; that his sick and attendants were armed, though some could not stand; that he was under fire, as all were; and that he behaved most gallantly.

Very respectfully,

E. A. CARR,

Brigadier-General, United States Army, Retired; Brevet Major-General, United States Army and United States Volunteers; Congressional Medalist; commanding at the times referred to.

On motion of Dr. PARKER SYMS, the report was received and ordered placed on the minutes of the society, and a copy sent to the family of the late Dr. McCreery.

(To be concluded.)

Book Notices.

Handbook for the Hospital Corps of the United States Army and State Military Forces. By CHARLES SMART, Deputy Surgeon-General, United States Army. New York: William Wood & Co., 1898. Pp. vii-350.

THE original handbook which Dr. Smart prepared for the instruction of the hospital corps of the United States army, when that body was organized by the government, proved itself a manual of much usefulness. It was but natural, therefore, that a revised edition should be demanded on the outbreak of the recent war with Spain, to the end that those who enlisted in the corps might have a compact and yet a thoroughly ample manual covering their field of duty. If we may judge by popular report of what has occurred of late in camp and in hospital, it would seem that this book has not had a wide army circulation, or else that its teachings have been singularly disregarded. Surely no intelligent man, whatever his military rank or corps, could read this book save to his benefit and to that of others. It is a most practical, simple, and straightforward presentation of military hygiene, medicine, and surgery adapted to the uses and the comprehension of men not technically trained in medicine.

The book consists of three divisions, of which the first deals with military hospitals and hospital duties, service in the field, camps, prevention of camp diseases, camp hygiene, and the like. The second part treats of anatomy and physiology in the rudimentary manner customary in instructing nurses. The third part applies to the special duties of the hospital corps in the management of cases, and to all intents and purposes comprises what ordinarily is taught as "first aid to the injured."

Dr. Smart has done his work well, and the book is both valuable and interesting; indeed, to read it is no task, but a pleasure, so agreeable is the writer's style. How valuable a trait this is is self-evident when one remembers that the work is designed for the non-professional reader; though, in truth, we think that many a military doctor might read the book to his profit. It is in the so-called militia that this book can bring about much good. The sad experience of recent months would have been almost an impossibility had simple yet vital

instructions, such as this book contains, been generally known. Indeed, it seems as if in future emergencies of the kind there should be required, not alone of medical officers, but also of line officers and of all in whose charge rest the health and the lives of men, a thorough familiarity with a work such as this.

Ensayo de una Higiene de la Intelección. Contribución al estudio de las relaciones que existen entre lo físico y lo moral del hombre, y manera de aprovechar estas relaciones en beneficio de su salud corpórea y mental. Por el Doctor NICASIO MARISCAL Y GARCIA, Director-Jefe del Laboratorio Central de Medicina Legal, etc. Madrid: Ricardo Rojas, 1898. Pp. 551.

INTELLECTUAL hygiene is an interesting topic about which we hear much and see little. Ever since the days of the Greek philosophers the conflict between high living and high thinking has been a favorite subject for those who knew much and those who knew little and who were desirous of imparting that knowledge to the world. The reviewer may possibly be pardoned if he ventures the opinion that Spain has not succeeded where others have failed. Our author has conscientiously tried to solve the knotty problems continually presented to those who endeavor to lead the intellectual life, but he gravely acknowledges the difficulty of deciding whether the intellectual man should marry, how much he should eat and drink, and how he should live. He also expresses a doubt, which in these regenerate days must be regarded as the rankest heresy, that women are not mentally equipped to lead the higher life, but must be content to act out a simple existence. Despite these blemishes, the volume may be recommended as a storehouse of the results of a vast amount of reading and study of the ancient and modern literature of the subject.

La Grippe. PAR L. GALLIARD, Médecin de l'Hôpital Saint-Antoine. Avec 7 figures dans le texte. Paris: J. B. Baillière et fils, 1898. Pp. 5 to 100.

THIS small monograph belongs to a series of similar volumes intended to present the more recent medical facts in a clear and concise way. They do not correspond to the familiar "quiz compend," but aim rather higher, contain references to the literature, and are confined to a single disease, which thus receives fuller treatment than is granted in any but the largest treatises on medicine. An excellent and up-to-date article on influenza is contained in this volume, giving in a very comprehensive manner all that is definitely known about the disease.

Elements of Sanitary Engineering. By MANSFIELD MERRIMAN, Professor of Civil Engineering in Lehigh University. First Edition. New York: John Wiley and Sons, 1898. Pp. 5-216.

THIS is a good book for any man to read, although it is primarily intended to be used as a text-book for students of sanitary engineering. It deals with those fundamental principles of water supply and sewerage that should be parts of a general education, but of which too many of us are fearfully ignorant. It brings home to us the wonderful advance in sanitary science that has taken place in the latter half of this wonderful century, and it is written in such a clear and easy style that one may read it through without loss of interest or fatigue.

The introduction defines sanitary science as embracing "those principles and methods by which the health of a community is promoted and the spread of disease is prevented." What the physician is to the individual the sanitary engineer is to the community, and so well has he done his work that in this country the average length of human life has been increased four years in the last half century. Let us, then, do our part by getting an intelligent understanding of the great principles of sanitary science, so that we can more efficiently co-operate with him.

Wesen, Ursache und Behandlung der Zuckerkrankheit (Diabetes mellitus). Von Dr. ALBERT LENNE, in Bad Neuenahr. Berlin: S. Karger, 1898. Pp. iv+152.

THE subject of diabetes mellitus is undoubtedly popular at present, the current medical periodicals rarely permitting a month to pass without some article on the subject, while several large volumes have recently appeared wholly devoted to this disease. Nevertheless this small monograph is a welcome addition. It is brightly and clearly written, and the author's experience has been unusually large, so that his views on the subject, though somewhat out of the ordinary, have a clinical foundation. In the section devoted to purely theoretical considerations on the nature of the disease, he differs sharply from von Noorden and other authorities, though only on minor points. The chapters on symptoms, on the method of reaching a prognosis, and on treatment are the best in the book. The author has slight faith in drugs, with the exception of opium, and in fact does not regard the latter with so much favor as is usually accorded to it. Diet, climate, and mineral waters are the three mainstays. A long series of analytical tables of food products, arranged so as to lighten the labor of making up a dietary, completes the book, which should be read by all those interested in the treatment of the disease.

The Office Treatment of Hemorrhoids, Fistula, etc., without Operation, together with Remarks on the Relation of Diseases of the Rectum to other Diseases in Both Sexes, but especially in Women, and the Abuse of the Operation of Colostomy. By CHARLES B. KELSEY, A. M., M. D., Late Professor of Surgery at the New York Post-graduate Medical School and Hospital, etc. New York: E. R. Pelton, 1898. Pp. 9 to 68.

THESE three lectures on the office treatment of hemorrhoids, fistula, etc., without operation are an outcome of the author's large experience in such work, and as such are to be commended to the thoughtful consideration of all those interested in the subject. The book is unusually well printed and bound.

Ueber Spermatocystitis Gonorrhoea. Von Dr. WALTER COLLAN, Assistent der dermatologischen Klinik in Helsingfors. Mit einer chromolithographischen und einer Lichtdruck-Tafel. Hamburg und Leipzig: Leopold Voss, 1898. Pp. 73.

THE attention of the students of genito-urinary diseases has, in the past few years, been largely directed to the study of the little-known changes which take place in the vesicula seminalis as a result of acute or chronic gonorrhoeal inflammation, and the problems are by no means completely disposed of. The pamphlet before us

is devoted to a discussion of the results obtained from the clinical and pathological examination of fifteen cases of the disease. Interesting observations are given on the anatomical relations and position of the seminal vesicles, and their inaccessibility to the ordinary examining finger is rather conclusively shown. For the purpose of massage and "stripping" of these organs the author recommends the instrument devised by Feleki as the simplest and best. The chapters on symptoms and treatment contain nothing original.

L'Occlusion intestinale. Par M. D. BAUBY, Chef des travaux de médecine opératoire à la Faculté de Toulouse, etc. Paris: Masson et Cie., 1898. Pp. 5 to 206. [*Encyclopédie scientifique des aide-mémoire.*]

THIS little volume is a type of those, now so common, which afford a very superficial view of the subject they are presumed to treat of, but are in no way to be considered as replacing larger and more thorough works on the same topic. The ground of intestinal obstruction has been very fairly covered in this volume, however, and it may prove useful to the student searching for the shortest road to medical wisdom.

Énergétique musculaire. Par M. F. LAULANIE, Professeur de physiologie à l'École vétérinaire de Toulouse. Avec une préface par M. A. CATAVEAU, Membre de l'Institut. Paris: Masson et Cie., 1898. Pp. 5 to 206. [*Encyclopédie scientifique des aide-mémoire.*]

A SHORT but useful collection of the facts concerning muscular energy is contained in this little work. It is divided into three sections. The first treats of the sources of muscular energy, the second of the work produced by the expenditure of this energy, and the third of muscle thermodynamics. The treatment is entirely free from mathematics of any sort, and a rather scanty recognition is offered of the many recent discoveries in physiological chemistry.

Laboratory Work in Physiological Chemistry. By FERDINAND G. NOVY, Sc. D., M. D., Junior Professor of Hygiene and Physiological Chemistry, University of Michigan. Second Edition, revised and enlarged. With Frontispiece and Twenty-four Illustrations. Ann Arbor: George Wahr, 1898. Pp. 7 to 326.

THE importance of a knowledge of physiological chemistry—as thorough as the nature of the subject will permit—on the part of the physician, and primarily on the part of the student of medicine, is not to be gainsaid. It is, of course, true that physiological chemistry is for the greater part a science of relatively recent growth. At present, however, the law of inertia too often shows itself by a contentment of the physician with so much of physiological chemical knowledge as is comprised in urinalysis, and no more. No doubt the extension of laboratory work in our medical schools will ere long correct this tendency, and to this end works like that of Dr. Novy will much contribute. The work in its present form is a considerable expansion of the first edition, but, at the same time, of the same general character and usefulness. It is, primarily, of course, an adjunct and a guide for the laboratory, but, while the full utility will not be evolved without the practical application of its teachings, it is a work which those who are not students may read to their profit, even though

their laboratory facilities be trifling or altogether wanting. The practitioner, therefore, is by no means excluded from participation in the assistance the book affords.

Hernies. Par Dr. PAUL BERGER, Professeur de clinique chirurgicale à la Faculté de médecine de Paris, etc. Extrait du *Traité de chirurgie*. Deuxième édition. Paris: Masson et Cie., 1898. Pp. 23 to 402.

THIS scholarly and practical volume is the section on hernia from the large *Traité de chirurgie* edited by Duplay and Reclus, which has been issued separately. It is a tribute to the experience and study of its author, and is certainly one of the best and clearest of the shorter works on the subject. The illustrations are excellent, the print is good, and the whole work has been brought up to date.

A Laboratory Guide in Uroanalysis and Toxicology. By R. A. WITTHAUS, A. M., M. D., Professor of Chemistry, Physics, and Toxicology in the Medical Department, Cornell University, etc. Fourth Edition. New York: William Wood & Co., 1898. Pp. vi-111.

THIS book seems to be intended chiefly for the use of students in the medical department of Cornell University. It therefore very properly emphasizes chiefly those time-honored methods of procedure with which every student must become familiar before he can proceed to new fields of exploration and conquest. The book is of handy form for its purpose, and contains blank pages for notes. The orthography is somewhat less conservative than the text, for we are introduced to "bromids," "cyanids," and "strychnin."

BOOKS, ETC., RECEIVED.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by Thomas L. Stedman, M. D. In Twenty Volumes. Volume XVII. Infectious Diseases and Malignant New Growths. New York: William Wood & Co., 1899. Pp. vi-3 to 715.

Diseases of the Eye. A Handbook of Ophthalmic Practice for Students and Practitioners. By G. E. de Schweinitz, A. M., M. D., Professor of Ophthalmology in the Jefferson Medical College, etc. With Two Hundred and Fifty-five Illustrations and Two Chromolithographic Plates. Third Edition, thoroughly revised. Philadelphia: W. B. Saunders, 1899. Pp. 7 to 696. [Price, \$1.]

Holden's Human Osteology: Comprising a Description of the Bones, with Delineations of the Attachments of the Muscles, the General and Microscopic Structure of Bone, and its Development. Edited by Charles Stewart, F. R. S., Hunterian Professor of Comparative Anatomy and Physiology, Royal College of Surgeons of England, etc., and R. W. Reid, M. D., F. R. C. S., Regius Professor of Anatomy in the University of Aberdeen. Third Edition. London: J. & A. Churchill, 1899. Pp. ix-358. [Price, \$5.25.]

Ocular Therapeutics for Physician and Students. By F. W. Max, Ophthalmologist, M. D. (Minden, Germany), Late Assistant Physician in the Ophthalmological Clinical Institute of the Royal Prussian University of Berlin, etc. Translated and edited by Charles A. Oliver, A. M., M. D. (Cincinnati), one of the Ophthalmic Surgeons to

the Philadelphia Hospital, etc. Philadelphia: P. Blakiston's Son & Co., 1899. Pp. xv-9 to 274. [Price, \$1.75.]

A Practical Handbook on the Muscular Anomalies of the Eye. By Howard F. Hansell, A. M., M. D., Clinical Professor of Ophthalmology, Jefferson Medical College, etc., and Wendell Reber, M. D., Instructor in Ophthalmology, Philadelphia Polyclinic and College for Graduates in Medicine, etc. Twenty-eight Illustrations and One Plate. Philadelphia: P. Blakiston's Son & Co., 1899. Pp. 9 to 182. [Price, \$1.50.]

A Text-book of Mechano-therapy (Massage and Medical Gymnastics). Especially Prepared for the Use of Medical Students and Trained Nurses. By Axel V. Grafstrom, B. Sc., M. D., Late House Surgeon, City Hospital, Blackwell's Island, New York. With Eleven Pen-and-ink Sketches by the Author. Philadelphia: W. B. Saunders, 1899. Pp. 5 to 139. [Price, \$1.]

Manual of Clinical Chemistry. By Elias H. Bartley, B. S., M. D., Ph. G., Professor of Chemistry and Toxicology in the Long Island College Hospital, etc. Thirty-three Illustrations. Philadelphia: P. Blakiston's Son & Co., 1899. Pp. vi-9 to 150. [Price, \$1.]

The Pocket Therapist. A Concise Manual of Modern Treatment, for the Physician and Student. Arranged Alphabetically for Ready Reference. By Thomas Stretch Dowse, M. D., Fellow of the Royal College of Physicians of Edinburgh, etc. New York: Wilbur B. Ketcham, 1899. Pp. 7 to 179. [Price, \$1.50.]

Transactions of the American Climatological Association. For the Year 1898. Volume XIV.

The Early Diagnosis of Cancer of the Stomach. By Charles D. Aaron, M. D., of Detroit. [Reprinted from the *Journal of the American Medical Association*.]

Caries of the Teeth and Diseases of the Stomach. By Charles D. Aaron, M. D. [Reprinted from the *Charlotte Medical Journal*.]

Albuminuria during Pregnancy, without Convulsions of the Mother, but with Eclampsia of the Newborn Infant. By Henry Kreutzmann, M. D., of San Francisco. [Reprinted from the *Archives of Pediatrics*.]

Diabetes Mellitus and Carcinoma Uteri; Hysterectomy; Recovery. By Henry Kreutzmann, M. D. [Reprinted from the *American Journal of Obstetrics and Diseases of Women and Children*.]

Torsion of the Pedicle of an Ovarian Tumor, with Acute Symptoms. By Henry Kreutzmann, M. D. [Reprinted from the *Pacific Record of Medicine and Surgery*.]

The Caustic Action of Arsenic in treating Carcinomatous Growths Accessible from the Surface of the Body. By C. W. Simmons, M. D., of Philadelphia. [Reprinted from the *Hahnemannian Monthly*.]

Some Preventives. By A. Jacobi, M. D. [Reprinted from the *Philadelphia Medical Journal*.]

Experimental Researches about Mixed Infection in Chronic Pulmonary Tuberculosis. By C. Fisch, M. D., of St. Louis. [Reprinted from the *St. Louis Medical Review*.]

The Porro Operation versus Total Hysterectomy. By H. J. Boldt, M. D. [Reprinted from the *Transactions of the American Gynecological Association*.]

Some Sources of Failure in treating Lacrymal Obstructions. By Leavitt Connor, M. D., of Detroit. [Reprinted from the *Journal of the American Medical Association*.]

Mechanical and Surgical Treatment of Fractures of the Neck of the Femur. By Arthur J. Gillette, M. D.,

of St. Paul. [Reprinted from the *Northwestern Lancet*.]

Entotical Sound Perceptions. By Lewis S. Somers, M. D., of Philadelphia. [Reprinted from *Medicine*.]

Miscellany.

The Infrequency of Typhoid Fever in Infancy.—Dr. John Lovett Morse and Mr. Hartley Wales Thayer (*Boston Medical and Surgical Journal*, January 12th), as a result of investigations made by means of Widal's serum reaction on fifty cases of suspicious gastro-enteric disturbances in children, arrive at the following conclusions: 1. Typhoid fever, as has been commonly believed, is an unusual disease in infancy. 2. It is possible that women whose blood gives a positive Widal reaction, even though it be years after the occurrence of the disease, may in some way transmit this to their infants.

Strontium in the Treatment of Acute Nephritis.—Dr. J. M. Da Costa (*Dunglison's College and Clinical Record*, December, 1898), in a clinical lecture delivered at the Pennsylvania hospital, said that in a case of acute nephritis he had found, from experience, the following treatment to be eminently satisfactory. He gave pilocarpine, hypodermically, every two hours, until he secured free action from the skin. If preferred, the pilocarpine might be given by the mouth; but he preferred, in these cases, to give the first dose hypodermically. In addition to this, he gave the lactate of strontium, fifteen grains at a dose, four times daily. This drug was one of the most efficient, non-irritating diuretics that we possessed; in addition, he was a believer in dry cupping over the kidneys, and in the use of hot vapor baths.

There were three drugs in acute nephritis which, to his mind, stood out with considerable sharpness above all others for efficiency—pilocarpine, digitalis, and strontium. He was particularly pleased with the value of strontium, which he considered indispensable in many of these cases. In this case they found that the quantity of urine, under this treatment, had steadily and rapidly increased from eight ounces on the first day to thirty-six ounces daily, then to forty-four ounces, then up to fifty-five ounces, while for the last twenty-four hours the patient had voided thirty-five ounces, with diminution the resident explained by the fact that the patient was given a hot bath. As to the increased color of the urine, it now contained the normal quantity of urea; there were still some albumin and tube casts, but the blood had disappeared. He directed the continuance of the treatment, keeping the patient on a milk diet, and using dry cups over the kidneys.

Successful Operation for Cerebellar Abscess.—Dr. J. H. Nicoll (*Glasgow Medical Journal*, January), related the following case to the Glasgow Medical and Surgical Society on November 4, 1898:

"The patient, aged twenty-five years, was first seen on May 17, 1898, and was found to be suffering from a discharge from the left ear, accompanied by dizziness of ten years' duration. For one month, also, there had been pain in the ear, general headache, and distention of pupils. A week later these symptoms became associated with vomiting, shivering, tenderness over the mastoid process, and drowsiness. On the following day the

antrum was opened by Dr. Barr and cleared of pus. It was then packed. In the next two days the patient became more apathetic, nystagmus developed, and the left pupil was variable in size. There was commencing optic neuritis in the left eye, and later on in the right. There was also repeated yawning. On the third day the left pupil became twice as large as the right. The temperature was subnormal, and the pulse 96. Dr. Nicoll then operated, opening up the mastoid orifice and exploring the sinus to the depth of an inch. As no pus was found, and as the bone was very dense, he trephined at first over the auditory meatus, and then just at the edge of the occipital bone. In the latter situation an abscess was found and evacuated.

"Progress to recovery, during which a drainage tube was kept in, was uninterrupted, but very slow; and, therefore, about six weeks afterward, Dr. Nicoll operated again, working into the cerebellar fossa round the knee of the sinus, having opened it from just behind the auditory meatus, thus tapping the abscess and making the two channels communicate. This cavity was douched out for some time. The man is now well, but the mastoid communication with the middle ear is still kept open. There were about twelve cases on record of recovery from cerebellar abscess after operation."

The Trend of Modern Medical Journalism.—An interesting article on the tendencies in Medical Journalism appears in the *Boston Medical and Surgical Journal* for January 5th, from which we quote the following practical remarks: "To our mind the weekly journal has another and even more important function to perform than the publication of original papers, and one which is of continually growing importance, not only to the medical profession but to the community at large. We refer to the power it has, or should have, in influencing public opinion toward high standards of ethics in medical matters and hygiene in the broad sense. This is the sole prerogative of the weekly medical journal, and one of the directions toward which it is more and more tending. Here we have a field of usefulness which is quite unlimited and which may, no doubt, be cultivated much more assiduously than it has been up to this time. A good sign in this direction was the active participation of our leading weekly medical journals in the discussion growing out of the medical management of the army in the recent war with Spain. Arduous as certain of these discussions were, they all tended toward a good end—namely, a clear expression of opinion on a point of public importance. As most of our religious contemporaries have left the bounds of the strictly churchly and entered a larger sphere of human interest, so may we look for an expansion of the scope of the medical journal to include matters of public concern which are in any way associated with the progress of medicine. The tendency in the future will be toward a closer scrutiny of the editorial pages and a demand for a definite expression of opinion on topics of general public concern. Here lies the opportunity of the weekly journal, and its success will be measured by the clear appreciation of this fact by its editors. It will not rise to this opportunity, we think, if it is to be a mere digest, and we shall be obliged to either ignore its extreme practical importance, which is fatal with respect to its value, or to make it a more definite and useful organ."

A Chinese Medical Journal.—We have from the *British Medical Journal* for December 17th, 1898, the first number of a new monthly journal, entitled "The Chinese Medical Journal," published by the Chinese Medical Association, 1, Victoria Road, Singapore.

ly *Journal of Medicine, Surgery, and Hygiene*, has just appeared. It is edited by Wan Tün Mo, a diplomate of the Imperial Medical College, Tientsin, and resident surgeon Alice Memorial Hospital, Hongkong. The publication of this journal, says the *British Medical Journal*, marks an epoch in the history of western medical science in China. Slowly but surely the more enlightened Chinese are becoming convinced of the superiority of western methods of medicine, surgery, and hygiene. In the first issue the scope and object of the magazine are set forth in the following passage: "The journal is published solely for advancement of medical science, and all contributions to its pages must be in strict harmony with the great facts on which true medical science is based with special reference to the facts of anatomy, physiology, botany, chemistry. Each issue is to consist of six sections: 1. Leading articles and translated selections from recognized authorities in the medical world. 2. Special cases and treatment. 3. To deal with new methods. 4. To give instruction in first principles of anatomy and physiology. 5. Notes on laws of health, food, sanitation. 6. Miscellaneous, including news of special interest to students of medicine. Western doctors in China will be asked to report cases of special interest. Illustrated plates and diagrams will be used." The first issue contains three leading articles—two from western sources treating of diagnosis and the treatment of disease; the third is an exhaustive inquiry into the nature and causes of bubonic plague. There is also an introductory article on the study of anatomy and physiology. The section on hygiene treats of impurities in water and maladies to which they give rise; preservation of eyesight, means of maintaining the body in health, and the importance of pure air. Dr. Wan, the editor, is a man of large professional experience, and it is hoped that his new venture will have great success.

The Advantages of a Knowledge of the Patient's Constitution.—There is so much truth in the following from the *Philadelphia Medical Journal* for December 24th that we reproduce it in its entirety:

"The power of resisting shock and infection varies widely, as is well known, among different races and among different people of the same race. The Irish are thought by some to be abnormally susceptible to shock, infection, or injury, while Oriental races are almost absolutely impassive under like conditions. An instance of unusual vitality is reported by Bidie, of the Indian Medical Service, in the *Indian Lancet* of November 1st: A native boy, aged fifteen, was gored by a bull in the abdomen, making a wound through which the intestines protruded and tearing the gut in several places. The coils of intestine were snared by the natives with *cow dung*, covered with a piece of coconut and some leaves, and the boy was carried five miles in a country cart over rough roads, reaching the hospital about six hours after the time of injury. The parts were cleansed, the intestines sutured, the abdomen was closed, and the wound dressed antiseptically. Shock was entirely absent, and the patient made an uneventful recovery, with rise of temperature only on three occasions after the operation.

"Unfortunately for both patient and surgeon, constitutions of such staying power are unusual, but this makes all the more imperative the cultivation of such surgical judgment as will enable one to predict with a fair amount of accuracy a patient's capacity to withstand surgical shock before undertaking operations of

expediency. There is some justification for the much-abused saying, that such a doctor 'knows the constitution of the family'; long acquaintance does help us to understand the personal equation. It is probable that more earnest, conscientious effort on the part of the surgeon, exercised every day in every case, to try to estimate the physical peculiarities of patients, would succeed in training the faculties so that the limits of intervention might, in certain cases, be extended, and in other cases sad accidents might be avoided."

The Teaching of Physiology in our Public Schools.—We have ourselves had something to say on this subject, and have protested against an unfair use of this vantage ground for exploiting the fads of cranks of whatever kind. We are glad to welcome the support of our excellent contemporary the *Philadelphia Medical Journal*, which in its issue for December 24th has the following pertinent remarks:

"In some States, we believe, it is obligatory that the text-books on physiology, made to order for the public schools, shall inculcate certain doctrines as to the use of alcohol and tobacco that represent merely the views of the minority on these subjects. The older children themselves, it is said, resent the expression of views found in these books as reflecting on the opinions and customs of their parents in their own homes. If a little learning is ever a dangerous thing it is so certainly in the case of medical and physiological science. The teaching of physiology to public-school children by teachers who themselves are profoundly ignorant of the subject must be superficial in the extreme. One of the faults of our public-school systems is the tendency to do too much, and to do it in a merely routine and mechanical manner. When, however, this teaching is made the means of propagating the individual views of faddists and theorists, the evils are twofold. First, the knowledge inculcated is likely to be false or misleading. Second, the doctrines are likely to repel intelligent scholars and drive them to the other extreme than the one aimed at. We think it goes without saying that all partisan questions, whether in politics, theology, or hygiene, have no place in the curriculums of our public schools."

The Toxæmic Factor in Diabetes Mellitus.—Dr. G. W. McCaskey (*Medicine*, January) thus sums up, in a paper read before the Northwestern Ohio Medical Association, a clinical study of this subject: The following conclusions appear to be warranted: 1. That all cases of persistent glycosuria are cases of diabetes mellitus, of varying grades. 2. That diabetes mellitus is a disease of diverse origin, the unity of the clinical picture being for the most part dependent upon the glycaemia and glycosuria, which are mere incidents, although dominating factors of the disease. 3. That phloridzin diabetes is not essentially different from clinical diabetes, and that it renders plausible the assumption of a chemical factor, either as a primary or as an important secondary cause in the clinical type of the disease. 4. That normal sugar transformation in the blood, the failure of which is responsible for the glycaemia and glycosuria, is the result of a chemical product in the blood, derived in man principally if not exclusively from the pancreas, and thrown directly into the blood from the pancreatic cells, without the intervention of the duct. 5. That the direct chemical antagonism of this chemical substance by another is no more improbable than such antagonism of a toxine by an antidote, which Martin has recently established. 6. It is probable on both clinical and experi-

mental grounds that certain chemical poisons, for the most part of gastro-intestinal origin, but possibly also from faulty tissue metabolism, or as a perverted "internal secretion" from glands, not necessarily ductless, either directly or indirectly antagonize, in whole or in part, the sugar-destroying substance in the blood, thus giving rise to glycaemia and glycosuria, and thus either primarily causing or at least exaggerating the clinical phenomena of diabetes mellitus, in a certain group of cases. 7. If further investigations should corroborate the conclusions here provisionally set forth, it would be advisable hereafter to investigate the bacteriology of the stomach and intestines in cases of diabetes mellitus, and if evidences of virulent bacterial, protozoal, or parasitic growth are found, these conditions should be met by suitable treatment, not with the expectation of entirely supplanting dietetic treatment, but as an important auxiliary to the latter, possibly rendering its restrictions less severe, with less resulting impairment of nutrition.

The Philosophy of Play.—In a very interesting article by Luther Gulick, in *Appleton's Popular Science Monthly* for October, the genetic idea of play is elaborated. The body in reaching adult age must rehearse the history of the race. It starts from a single cell and ends in the most elaborate differentiation. Not only does the body rehearse the life of the race, but the mind also, and the plays of children are the history of these forgotten activities. Thus it is that hunting, fishing, sailing, swimming, mountain climbing, and the like are all aspects of our past history, and are pleasurable because in the unconscious memory they are associated with the organism's past welfare. Play is therefore the ontogenetic rehearsal of the phylogenetic series, and the satisfaction that it gives proceeds from the gratification that comes from realizing anew these deep elemental racial functions.—*Southern Practitioner*, January.

When to Operate in Appendicular Disease.—Dr. A. Morgan Cartledge (*Memphis Lancet*, January) draws the following conclusions: 1. Probably ninety-eight per cent. of the patients who die of acute appendicitis without operation have the fulminating variety of the disease; operation to be of service must be done in the first twenty-four hours—better the first twelve. 2. In view of the fact that we have no means of knowing the probable course of a given attack of appendicitis, operation, when possible, should be performed within the first twenty-four hours after the onset of symptoms. 3. Patients seen after the third day should not be operated upon until after the attack, or until purulent formations, if such take place, have been walled off, and the patient practically rid of general sepsis. The exception to this rule is the rupture of an appendicular abscess into the peritoneal cavity (a very rare accident), when abdominal section should be immediately performed. 4. Probably as many patients recover from general septic peritonitis by stimulants and purgatives as by operations. In either event, if it is a case of true general septic peritonitis, the mortality will not be far from ninety-five per cent. Contributions to medical literature would indicate that there is a need on the part of the profession of more definite views as to the nature of this disease. If operated upon at all, no attempt at general cleansing of the cavity should be practised; quickly assist Nature to take care of the desperate patient by removing the source of the fire; to do more is to add the shock of an unnecessary operation

to that of an already nearly exhausted vitality. 5. Subject to interval operations patients who have suffered an unmistakable attack of the disease. 6. Don't operate too soon after a severe attack with many adhesions; the operation will be greatly simplified by waiting a few weeks longer; in the mean time keep the patient upon light diet and little exercise. Patients do not usually have a recurrence until the adhesions or splints have been removed by absorption. The mortality from interval operations should not be more than one per cent.

Gouty Angina.—Dr. R. Le Clere (*Normandie médicale*, December 15th) concludes a paper based on the observations of six cases in which pharyngeal manifestations preceded an attack of gout, and disappeared when the articular phenomena appeared, as follows: 1. There is such a thing as gouty angina. 2. This term should be applied only to such cases as are premonitory to an access of gout. 3. This angina is characterized in general by an intense congestion with edema, occupying the velum palati and even the laryngeal vestibulum. 4. The description of this angina corresponds to that of the so-called rheumatic angina as understood by Lasèque. 5. The duration of this congestion extends from some hours to three days. 6. It is not amenable to any special treatment, save to such derivative measures as may tend to hasten the articular determination, and in this it resembles rheumatic angina, which is not ameliorated by salicylate of sodium.

Lysol Poisoning following an Intra-uterine Douche.—In the *Centralblatt für Gynäkologie*, 1898, No. 39, Cramer reports the following interesting case: The patient, a primipara, aged twenty-two years, was taken in labor, examined by a physician at her home, and was sent to the hospital at Bonn, where it was found that she was seven months pregnant, in labor, the fetus presenting by the breech. The birth of the child was not specially difficult, and the placenta was entirely expelled without delay. The patient received a vaginal douche of one per cent. lysol. Several hours later she had fever and rapid pulse, and the uterus was washed out with lysol, one per cent. The uterus was strongly ante-flexed, and difficulty was experienced in introducing the douche tube. After a litre and a half of the solution had been used the patient suddenly became rest-less, breathed heavily, and became unconscious. The pulse was rapid and weak. In a few moments she regained consciousness and complained of giddiness. The pulse and temperature fell. Her child perished soon after birth, the autopsy revealing no cause for its death. The patient developed icterus and abdominal tenderness. The urine was dark brownish-black, full of casts and blood cells. There was considerable albumin present. An examination of the urine for phenol did not give a clear reaction. Tribromophenol was found, however, in considerable quantity. The patient died from exhaustion on the tenth day after confinement, with symptoms which would be difficult to explain clearly. On autopsy it was found that septic infection was present. At the fundus of the uterus there was an area of ulceration, from which thrombi had extended into the pelvic veins. There was also an acute hemorrhagic nephritis.

In commenting upon the case, Cramer calls attention to the condition of the urine, which contained albumin and abundant debris from the kidney. Regarding the manner in which absorption occurred when the douche was given, it is thought that lysol entered direct

ly into the blood current through surfaces opened by ulceration. Experiment has shown that the injection of carbolic solution into the blood-vessel of an animal causes sudden collapse, exactly like that observed in this case.

Whether this alone would have proved fatal is very doubtful. A severe septic process was present in the endometrium quite sufficient to have brought about a fatal result. There were reasons for believing that the birth had been criminally induced, and abundant opportunity for septic infection had occurred. An interesting symptom in the case was the strong, full pulse, which the patient had after the first shock following the injection. This is often seen in eclamptic patients, and is very significant of acute nephritis in the pregnant woman.

It has been Cramer's custom to employ intra-uterine douches of from 0.5 to one per cent. lysol, using from ten to fifteen litres, and he has seen nothing but the best results from this usage. The case reported would not incline him to abandon this method of treatment.—*American Journal of the Medical Sciences*, January.

The Presence of Meconium from a Medico-legal Aspect.—Bestler (*Centralblatt für Gynäkologie*, 1898, No. 38; *American Journal of the Medical Sciences*, January, 1899) examined seventy-four newborn children to determine at what time the meconium is entirely discharged. He found that it is not expelled until the second or fourth day, and in children fed from the bottle as late as the fifth or sixth. It is evident that the presence of meconium is not a reliable sign of the age of the child.

Microscopical examination of the meconium showed epidermal cells, crystals of cholesterol, and lanugo hairs. Meconium corpuscles were also present.

Honors for Sir Henry Thompson, F. R. C. S.—According to the *Lancet* for January 7th, Sir Henry Thompson, the well-known genito-urinary specialist, of London, has been promoted to a baronetcy.

A Curious Case for Forensic Medicine.—According to the *Gazette médicale de Paris* for December 17th, Professor Lacassagne recently examined at Lyons the cadaver of a man taken from the river Saône whose trunk was surrounded by an enormous serpent. The cadaver was mummified, and it was thought must have been at least two years entombed. A professional naturalist stated that the serpent was a boa of Senegal. It had not been dead more than a month at the outside. M. Lacassagne thinks that the corpse was probably that of a suicide which, for some reason or another, had been retained at the bottom of the water for a long time until it was brought to the surface by a swell. By mere chance the boa, thrown probably into the Saône by the proprietors of some traveling menagerie, must have encountered the cadaver. The affair has caused considerable interest, attracting crowds to the morgue.

A Street to be named after Charcot.—According to the *Gazette médicale de Paris* for December 17th, M. Rançon has made a proposal to the Municipal Council of Paris to have the rue Campagne-première named after Charcot.

A Medical School for Tonquin.—The *Gazette médicale de Paris* for December 17th informs us that M. Doumer has a project for creating a native school of medicine at Hanoi.

A Monument to Charcot.—According to the *Gazette de gynécologie* for December 15th, the inauguration of the monument to Charcot before the Salpêtrière Hospital took place under the presidency of the minister of public instruction on December 4th.

The University of Leipzig.—According to the *Gazette de gynécologie* for December 15th, Professor Röntgen, the discoverer of the X rays, has been called from the University of Würzburg to the chair of physics at Leipzig, and has accepted the office.

The Doctor in Drama.—According to the *Gazette médicale de Paris* for December 17th, Amédée Rolland recently had presented at the Odéon Theatre a drama likely, according to the critics, to be a success. *The Doctor's Holiday* is said to be a very strong work. A physician ruralizing at a friend's house observes that the husband is strangely falling off in health. The doctor studies him quietly. The patient's state seems inexplicable, when one day the physician discovers poison in a glass of water brought to him by his wife. The woman is jealous of a fair friend and is slowly poisoning her husband. From this point begins a struggle between the jealous wife, who wishes to kill her husband without saying anything, and the physician, who essays to save him without incriminating her. In the end the physician restores the almost dying man to life; brings back the wife to her duty with profound remorse; and she, so lately criminal, now becomes devoted, humbly repentant, and ready to atone for a week of horror by an entire life of devoted self-abnegation. The rival takes herself off, and the good doctor has not lost his holiday.

The Hospital Ship Bay State.—The *Boston Medical and Surgical Journal* for January 19th is largely taken up with a very interesting series of illustrated articles descriptive of the hospital ship *Bay State*, which were read before the Boston Society for Medical Improvement on November 21st. The articles are: The Hospital Ship *Bay State*, by Dr. Herbert L. Burrell; Construction of the Massachusetts Hospital Ship *Bay State*, by Mr. J. T. Boyd, consulting engineer; The Medical Equipment, by Dr. E. H. Bradford; The Method and Character of Work done by the Massachusetts Hospital Ship *Bay State*, by Dr. Herbert L. Burrell; The Medical and Surgical History of the Hospital Ship *Bay State*, by Dr. J. T. Bottomley; The Duties and Work of the Purser of the Massachusetts Hospital Ship *Bay State*, by Mr. W. H. Seabury, volunteer purser; and The Nursing Care on a Hospital Ship, by Miss C. W. Cayford.

Dr. Reed's Sociological Study of "Christian Science."—Messrs. McClelland & Co., of Cincinnati, have published in pamphlet form Dr. Charles A. L. Reed's address entitled *Christian Science; a Sociological Study*. It is a strong arraignment of the peculiar sect. We understand that the pamphlet is to be had at a nominal price. It ought to be circulated extensively.

A New French Catalogue of Scientific Books.—Messrs. J. B. Baillière et Fils, of No. 19 rue Haute-Feuille, Paris, have recently issued their *Catalogue général des livres de sciences*, containing 112 double-columned pages and the titles, etc., of about five thousand works on medicine and the sciences. They offer to send it to any applicant who incloses postage stamps, French or foreign, to the amount of fifty centimes.

rounded or flattened tumor on the affected bone, due to the inflammatory swelling of the periosteal membrane and subsequent exudation. The subjective symptoms are slight; the patient's general condition remains good, and he usually continues to attend to his ordinary vocations. The inflammatory process begins in the internal layer of the periosteum, and gradually spreads through it and even to the subjacent bone. The termination may be in resolution and return to the normal, more especially if appropriate treatment is vigorously carried out; or suppuration may occur, with necrosis and exfoliation of the layer of bone thus cut off from its nutritive supply. Quite commonly, however, the process goes to neither extreme; a chronic and very slightly painful periosteal swelling persists; osteophytes are formed in the periosteal layers, and oval or hemispherical enlargements of the bone, the so-called syphilitic topi or nodes, are formed. In the same way a simple osteitis, very chronic and accompanied by but little pain and no general symptoms at all, may set in. The inflammatory process usually ends in sclerosis and eburnation; very rarely is there abscess formation, with caries or necrosis.

In the true gummatous periostitis the swellings on the bones gradually soften and assume a deceptive appearance of fluctuation; and the subjacent bone is almost always involved in the process. It may end in resolution, more especially when treated; but not uncommonly the skin over the tumor becomes thinned, reddened, and finally breaks, and the characteristic slimy, blood-stained, and purulent fluid exudes. The bone below is found carious, eroded, or perforated, and an exostotic wall surrounds the margins of the affected area. The cavity is finally filled up with granulations, developing into connective tissue. Thus bone scars, perforations of the flat bones, and other characteristic deformities occur.

Gummatous osteitis rarely occurs without simultaneous or antecedent involvement of the periosteum; but the process may begin in the interior of the bone in numerous small foci, and lead to destruction and rarification of the bone tissue. If the foci are not too large and numerous, the condition may occasion hardly any appreciable symptoms, save slight pain on percussion, and a normal or osteoporotic bone be left behind. If they are large and numerous, swelling of the bone with marked tenderness occurs; here the disease material may remain as cheesy foci after the process has ended; but more commonly necrosis and sequestrum formation occurs. The cavity left behind is usually only incompletely filled with connective tissue.

As regards the cranial bones more especially, syphilitic inflammations, either simple or gummatous, cause but little general disturbance when the external periosteum and table only are involved. When the internal table and membrane are affected cerebral compression may result; but even the severest cases react promptly to

appropriate treatment. The very worst cases of gummatous osteitis, however, ending in necrosis, may show hardly any symptoms during life. Thus Moore exhibited a skull at the London Pathological Society in which the entire calvarium was worm-eaten, the cavities being filled with gummatous material. The patient had exhibited no symptoms during life save two eczematike patches upon the scalp.

In gummatous osteitis and periostitis of the cranial bones the soft parts are usually gradually destroyed, and the dead bone appears as a blackened mass in the depths of the lesion. The course of the malady is extremely chronic, and many months usually elapse before the dead tissue is cast off. If the process is very extensive, and both tables are involved, the brain covered by the meninges is exposed when the necrotic bone comes away. Even in these cases, however, the ultimate result is usually good. The meninges rarely become involved; and while the defect in the skull is usually not filled in with bone, but with connective tissue, this thickens and contracts as it gets older, and finally forms a fairly good covering for the soft parts below. Surgical intervention for the removal of the dead tissue is rarely required.

The case represented in Figs. 1 and 2 is an interesting example of gummatous periostitis and osteitis and its consequences, which I saw through the kindness of Dr. R. Wolf of this city. The patient was a Russian woman about thirty-five years old, and her history, obtained only with difficulty and in an unsatisfactory manner, may be summed up as follows:

She had had trouble in the scalp twelve years before; but she was ignorant of its nature, and gave no history of other syphilitic manifestation. So little inconven-

FIG. 1.

ience had it given her that she had no distinct recollection of its having been treated. After many months a flat piece of bone had come away, and in the course of time the ulceration healed, and she had no further trou-

ble. A few months ago, without known reason, trouble began in the scar. Ulceration began in the centre and slowly spread, and, though it caused her but little inconvenience, she finally sought medical aid.

Examination showed that an area of the scalp of circular shape, about two inches in diameter and situated over the two parietal bones at their posterior superior margins, was entirely hairless, and was, in fact, a dense mass of white, adherent cicatricial tissue. In the centre of this was a large, oval, dark-brown, and greenish crust, from the edges of which pus welled out on pres-

FIG. 2.

sure. She positively refused to permit this crust to be removed, and no examination of the subjacent ulceration could be made. There could be no doubt, however, either as to the nature of the process or the condition under the crust. The patient was suffering from a recurrence of guminous inflammation in the scar; and the condition of the sequestrum from the old inflammation showed that the process must have reached very close to the meningeal membranes.

FIG. 3.

This sequestrum the patient exhibited with a good deal of pride, stating that she had earned it as a pocket piece, for good luck, ever since it had come away. It consisted of an irregularly oval and curved piece of bone, measuring two inches and a quarter by two inches. It was evidently composed of two adjacent portions of the posterior upper parts of the parietal bones, the post-

tal suture dividing them in the middle line showing beautifully. The upper convex surface showed the outer table of the skull intact. The under concave surface was composed mostly of cancellous tissue; only along the middle line at each side of the suture the inner table was present, and here, of course, the entire thickness of the skull was lost.

The course of the disease after treatment was instituted was quite uneventful. The suppuration stopped, the scab gradually became detached, the ulceration healed, and the parts returned to their former condition. The patient insisted on keeping her piece of bone.

The point of interest in the case is the demonstration of the fact that very extensive destruction of important tissues can take place in syphilis without any systemic reaction or even much personal discomfort. The first attack of osteitis had destroyed, in places, the entire thickness of the skull, and had necessarily exposed the meninges; yet the inflammation had not spread to those membranes, and the patient had not thought herself sick enough to be under medical care. Pain, after all, is the chief of the subjective symptoms; and its almost entire absence is responsible for the extent of the lesion that I have described.

AN

INTERESTING CASE OF HYDRONEPHROSIS.

By JOHN S. PYLE, M. D., LL. B.,

TOLEDO, OHIO.

THE accompanying illustration is a reduction from a photograph of an enormous kidney which I removed from an unmarried woman in the month of June, 1898. The case is one of interest because of the size, the almost negative history, and the probability of one mistaking the growth for an ovarian tumor. The diagnosis of an ovarian growth had been repeatedly made before the patient came under my observation, and, on two occasions, the common mistake of pregnancy had been made. The latter, of course, was hardly excusable; for, aside from the abdominal enlargement, there were no other signs of this last-named condition. On the other hand, it was impossible to say that the growth was not ovarian. The enlargement occupied the middle of the abdomen and extended below to the brim of the pelvis and above to the epigastric region. The patient, however, spoke of noticing a right-sided development high up and in the lumbar region; but as there was no history of well defined pain and symptoms of renal complication, this circumstance was not regarded as throwing much light upon a possible diagnosis. The tumor could be easily outlined, and, while the shape was that resembling a kidney, its unusual size and central position made the diagnosis a matter of doubt. In operating I chose the median line as the most suitable place to make the abdominal opening. After being done, I was soon apprised of the extent of the abnormal condition, and, in a matter of minutes, the specimen was in the anterior abdominal wall. I will now describe a brief opening in the peritoneum, and then state the nature and extent of the growth. The incision was made along the upper border of the rectus abdominis. The greater curvature of the stomach was drawn up to the incision, and represents the tubercles and is a typical case.

fire right lumbar and portions of the right hypochondriac and iliac regions, extending from and approximating the under surface of the right lobe of the liver to the brim of the pelvis, filling the right iliac fossa. The lesser curvature of the growth illustrated is nothing but

the distended pelvis of the kidney, and was that portion which gave prominence to the abdomen and occupied the central region. The weight of the growth after removal was ten pounds.

The size of the growth was composed of the cortex of the kidney with a complete destruction of the secreting substance. It was filled with a rimous fluid of a light-specific gravity. The operation was performed at the Audin Hospital at Canton, Ohio, and was uneventful. The patient recovered, and is now enjoying excellent health.

2123 A GRAND AVENUE.

A NEW STAIN FOR THE BACILLUS TUBERCULOSIS.*

BY MARION DORSET, M. D.

[Communicated from the Bacteriologic Laboratory, Bureau of Animal Industry, U. S. Department of Agriculture, Washington, D. C.]

There is a percentage of fat present in the bodies of tubercle bacilli which was first noted by Hammerschlag, Schmitt, and de Schweinitz and the writer, in the course of their recent chemical study of the tubercle bac-

cillus which is being carried out in this laboratory under the direction of Dr. de Schweinitz, found that the dried bacilli often contained as much as forty per cent. of ether soluble material. Reports upon some of the results so far obtained in the above-mentioned work have already been published by de Schweinitz, or de Schweinitz and Dorset, in the *Journal of the American Chemical Society*, 1895, 1896, and 1898, the *Centralblatt für Bakteriologie u. Parasitenkunde*, and in bulletins from this department.

In pursuance of a suggestion made in one of these earlier publications, that the large amount of fatty material in the tubercle bacilli probably accounted for the difficulty experienced in staining the bacillus with the ordinary dyes, an effort was made by the writer more than a year ago to stain them with some of the ordinary dyes after the preparations had been extracted with ether and alcohol for varying lengths of time. The results obtained, however, were not satisfactory.

Shortly afterward my attention was called to the statement that sudan iii was a useful stain for fat in histological and pathological work, and it was immediately tried upon preparations of the tubercle bacilli. This dye is insoluble in water, soluble, however, in alcohol with a red color, also in the various essential oils, in chloroform and xylol. Fat once stained with this material can be decolorized with difficulty. Dadd,* who first suggested the use of sudan iii in histological and pathological work, recommends that Müller's fluid and glycerin be used in hardening and fixing the tissues, and that absolute alcohol should not be used as a dehydrating agent, nor should the specimen be cleared in the essential oils or xylol nor mounted in Canada balsam. After trying various strengths of solutions of sudan iii in alcohol, it has been found that the following methods give the most satisfactory results:

I. *Staining of Tubercle Bacilli in Pure Cultures.*—Cover-glass preparations were made and fixed in the ordinary way and then immersed in a cold, saturated eighty-per-cent. alcoholic solution of sudan iii for five minutes. The excess of stain was then removed by washing in several changes of seventy-per-cent. alcohol for five minutes. The results obtained were very satisfactory, and the characteristic appearance of the tubercle bacilli could be very readily noted. The bacilli are stained somewhat better if left in the sudan iii for ten minutes and then washed in the seventy-per-cent. alcohol. The germs are found stained a bright red and the beaded appearance is very distinct. Cultures of the bovine tubercle bacillus, and also of the tubercle bacillus obtained from swine, treated with this dye, were not apparently as well stained as in the case of the bacillus of human origin. These results should be verified, however, and further work with these and tubercle bacilli

*Landerer paper presented at the American Public Health Association, held at Springfield, Mass., 1896, by Dr. E. A. de Schweinitz.

Tuberculosis.
Pure culture. Human.

Section from a tuberculous lung, human,
showing tubercle bacilli in
bronchial exudate.

Tub. Bacilli
in sputum, stained in Sudan III. Counter
stained with methylene blue.

DR. DORSET'S ARTICLE ON BACILLUS TUBERCULOSI

from various sources is in progress. The human tubercle bacilli stained with sudan iii are not decolorized by washing for two minutes with dilute one-to-twenty-five sulphuric, hydrochloric, or nitric acid, or ammonia.

II. *Staining of Preparations from a Gland of a Tuberculous Guinea-pig, and from Sputum, which had been proved to Contain Tubercle Bacilli.*—The preparations were fixed as usual and immersed for ten minutes in a saturated eighty-per-cent. alcoholic solution of sudan iii. They were then washed from five to ten minutes in seventy-per-cent. alcohol. Upon examination the tubercle bacilli were found to be stained a distinct red and presented the characteristic appearance. No other bacilli present in the sputum had been stained by the sudan iii, though they were evident in quantity when the preparation was counterstained with methylene blue. The tubercle bacilli still retained their characteristic red color and appearance.

III. *Sections of a Tuberculous Lung.*—Sections from the lung of a man who died of bronchial tuberculosis* were stained from five to ten minutes in a concentrated eighty-per-cent. alcoholic solution of sudan iii washed from five to ten minutes in several changes of seventy-per-cent. alcohol, counterstained with methylene blue, dehydrated with absolute alcohol, cleared with clove oil, and mounted in Canada balsam. In this preparation the tubercle bacilli were stained red and could be distinctly seen lying in the tissue. The material from which the sections were made was prepared in the following way: Pieces of the lung were placed in absolute alcohol and allowed to remain for a week, then changed into a fresh lot of alcohol, and from that passed through alcohol and ether into celloidin in the usual way. The sections after staining were also dehydrated with alcohol, but in spite of this fact the tubercle bacilli were well stained by sudan iii. It is thus evident that their staining properties are not influenced by the dehydrating action of the alcohol. This differs from the method prescribed by Daddi in staining sections for fat, as he recommends that care should be taken not to dehydrate with alcohol or clear with clove oil. Possibly the fatty material in the bodies of the tubercle bacilli is not as soluble as that deposited in the tissues. It should be noted, however, that preparation stained with sudan iii and mounted in Canada balsam did not retain a bright color after a month's time.

To demonstrate further that sudan iii is apparently a selective stain for tubercle bacilli, I endeavored to stain the numerous varieties of bacteria found in decaying sputa, pure cultures of bacilli, cholera, glanders, phoid, anthrax, symptomatic anthrax, diphtheria, and prodigious bacilli, the sporillum of *Vibrio cholerae*, and the *Staphylococcus pyogenes aureus*, with no effect. Preparations of the smegma bacilli were also

made, but did not stain with sudan iii, although they were stained with carbol fuchsin according to the ordinary method. In a mixed preparation of tubercle and smegma bacilli, stained with sudan iii and well washed with seventy-per-cent. alcohol, the tubercle bacilli appeared characteristic, while the smegma bacilli remained unstained, although this same preparation, when subsequently stained with carbol fuchsin, showed smegma bacilli present in abundance. It would appear from the results so far obtained that sudan iii may be considered as a selective stain for tubercle bacilli, and that this selective action is due to the large amount of fatty material present in the body of the germ. When stained with sudan iii the characteristic beaded appearance of the tubercle bacilli is very distinct, and, as has been suggested, this beaded appearance in the staining is probably due to the droplets of fatty substance present in the body of the germ. Although smegma bacilli stain very readily with carbol fuchsin, similarly to the tubercle bacilli, the fact that the smegma bacilli do not stain with sudan iii would indicate that their cell substance is very different from that of the tubercle bacilli.

The practical value of sudan iii as a stain for tubercle bacilli will be recognized where a rapid method is desired for staining the organism in tissues and for the purpose of differentiating without trouble between smegma and tubercle bacilli in cases, as in urinary sediments, where the smegma bacilli might be present, and throw some doubt upon a positive identification of the tubercle bacilli by the ordinary method of staining. The method takes about the same length of time as the carbol-fuchsin method for cover-glass preparations, but as the stain is apparently a selective one for tubercle bacilli, it appears to be well adapted for routine work.

August 18, 1898.

PRELIMINARY REPORT ON THE RESULTS OF BLOOD EXAMINATIONS AT CAMP WIKOFF.

AUGUST AND SEPTEMBER, 1898.

By JAMES EWING, M.D.

(Continued from page 148.)

PARASITOLOGY. 1. *Pl.* *Pl.* *Pl.* *Pl.* *Pl.* *Pl.*

The earliest forms of this parasite were small, rounded, bilobed, and contained a single nucleus. In the later stages they showed slight change of shape, becoming more elongated. At the same time they became more numerous, and the nuclei were more distinct. Small, evenly stained, and rounded bodies were also seen. At the same time the number of these bodies was greatly increased. The bodies were small, rounded, and contained a single nucleus. They were also seen in the blood of the same patient. The bodies were small, rounded, and contained a single nucleus. They were also seen in the blood of the same patient. The bodies were small, rounded, and contained a single nucleus. They were also seen in the blood of the same patient.

* The material was kindly furnished by Dr. Carroll of the Army Medical Museum.

blunt points. These bodies usually exhibited an active, rolling motion, but were sometimes sluggish, when they were seen to assume the form of the intracellular, spheroidal bodies.

During nearly all periods of the first two, or sometimes three, days after sporulation, the peculiar signet-ring form of the parasite was seen in the red cells. In the fresh condition this body appears indistinctly vesicular, is slightly amoeboid, and, especially in virulent infections, was wont to extrude short globular pseudopodia. In stained specimens, in cells flatly spread and instantly dried, this typical body has the appearance of a signet-ring, a quarter to two thirds the diameter of the red cell, the thickened portion of the ring, or signet, being usually very prominent, and the bow of the ring being exceedingly thin. It may exhibit one or more minute achromatic points, and one small deeply staining granule. There seems little room for doubt that this form of the parasite is really of the form of a ring, and not, as is sometimes stated, spheroidal with an achromatic centre.

The growth of the signet-ring body in the circulation appears to be slow, as they were usually seen of slightly increased size for two, and in six cases for three, days after sporulation (162, 500, 612, 646, 681, 782).

The largest signet-ring form seen in the present series were about four to five micromillimetres in diameter. They were almost invariably non-pigmented, but occasionally one or two fine pigment grains could be seen scattered along the periphery of the ring. Their position, projecting beyond the outline of the red cell, or apparently applied to the surface of the cell, is often characteristic.

The signet-ring form of the aetivo-autumnal parasite was readily distinguished from the early ring-shaped form of the tertian parasite on the following features:

(1) The tertian ring never shows a distinct signet on one side and an extremely fine, regular bow on the other, but is thicker and more irregular.

(2) The tertian ring very early exhibits a distinct spheroidal achromatic portion, which is absent or extremely minute in the aetivo-autumnal parasite. (Alcoholic eosin and methylene blue.)

(3) The tertian ring early produces many fine pigment grains, which are late and infrequent in the aetivo-autumnal ring.

(4) The red cell is usually shrunken when infected by the aetivo-autumnal ring, and nearly always swollen when harboring the tertian parasite.

The diagnostic value of a close scrutiny of these signet-ring form was strikingly illustrated in a case of quotidian aetivo-autumnal fever (338) in which, in the same red cell, two rings were found; one, three micromillimetres and a half in diameter, developed in a paroxysm, occurring thirty hours previously, and a second one, a micromillimetre and a half in diameter, coming

from a paroxysm about six hours before the examination of the blood.

In another case (67) of double infection, young crescents were found with great difficulty, but rings of both types were abundant, and readily distinguished on the above features. Later, adult forms of both varieties were seen.

After the second or third day, or in cinchonized cases often much earlier, the signet-rings usually disappear from the circulation, and their further development proceeds, if at all, in the viscera, especially in the brain, marrow, and spleen. In these situations the growth of the parasites may be followed in smears of the tissue made on glass slides and treated as blood specimens. In such specimens most of the later forms of the parasites can be seen simultaneously. Besides the rings, tissue smears usually contain many spheroidal, hyaline, pigmented, intracellular bodies, three to five micromillimetres in diameter. These bodies are probably the next developmental stage beyond the rings, but the gap between the ring form and the spheroidal pigmented body is very wide, and their supposed relation can not at present be claimed with certainty. From the pigmented spheroidal body all transition forms up to adult *crescents* are to be seen in abundance. Small pigmented spheroidal bodies were seen in the circulation in one fatal case of the present series (67), but are rare in the peripheral blood. From the third to the fifth day after sporulation *elliptical intracellular bodies* begin to make their appearance in the circulation. From the fourth to the sixth day crescentic forms are usually to be found, and thereafter in cinchonized cases, only adult or nearly adult crescents are usually to be seen. All these later forms are abundant in marrow smears.

The *segmenting forms* of the aetivo-autumnal parasite are almost never seen in the circulation, and were only once encountered there in the present cases. In the marrow smears from a fatal case (793), however, many aetivo-autumnal rosettes were seen. In eight of these the spores could be accurately counted, and their number was invariably eighteen. These rosettes were slightly smaller than the tertian rosette, a difference apparently due to the smaller size and lesser number of the spores. The pigment, composed of coarse, brownish-yellow grains, was usually centrally placed. Distinct remnants of the fib of the red cell were usually seen surrounding the rosettes.

In regard to the time required for the fertile cycle of the aetivo-autumnal parasite, the writer secured no evidence that it can transpire in the period usually ascribed—viz., forty-eight to seventy-two hours. In cases of quotidian and tertian fever from this infection, there was no indication that the new brood of parasites had developed from the generation of one or two days preceding, the larger signet-ring forms of these generations being usually still present in the circulation.

Moreover, the slow development of the ring forms, and the wide morphological gap between them and the rosettes, make it appear extremely improbable that the change from large signet-rings to rosettes could occur in less time than is required for the development of large rings from spores, which in six cases was found to extend over forty-eight hours.

It is possible, however, that the inhibitory influence of quinine may so retard or disturb the cycle that no reliable observations on this point were possible in the Montauk cases. It is possible also, though improbable, that the cycle in secondary paroxysms differs from that in primary seizures, very few of which were seen at Montauk.

With these possible sources of fallacy, it is the conclusion of the present study that the fertile aëstivo-autumnal cycle may require much longer than forty-eight hours, and that sterile forms are not fully developed until the end of six or seven days. Clinically, a great many cases showed characteristic attacks lasting seven days, followed immediately by relapses of equal duration. The periods given above for the appearance of various forms of crescentic bodies were verified by so many observations that the writer is convinced of their accuracy. Adult crescents appearing in the circulation before the end of the fourth day of the cycle are probably to be referred to a preceding generation of parasites.

2. *The Tertian Parasite.*—The earliest forms of the tertian parasite seen in the blood of the present cases were, as is usual, small, spheroidal, non-pigmented, intracellular bodies, slightly larger than the similar forms of the aëstivo-autumnal parasite. In all cases in which such forms were seen, larger and typical tertian rings were also found. The spheroidal, achromatic portion, which characterizes the tertian ring, develops with the increasing bulk of the parasite until, in the adult forms, it measures two to three micromillimetres in diameter, and exhibits a faint reticulum.

In the tertian presegmenting forms, the reticulum of the body of the parasite becomes very distinct, staining deeply with methylene blue, and at this stage the single achromatic portion appears to subdivide, and is found in the meshes of the reticulum.

The usual development of the tertian parasite was followed in many cases. In one particular, the Cuban tertian parasite appears to differ from that seen in the New York cases. In two fatal cases (130, 559), and in several very severe tertian infections, the parasites were much more actively amoeboid than the writer has ever seen in cases of New York malaria. On this account, in stained specimens, the pseudopodia of the larger parasites were extremely long and numerous, so that in some cells the body of the parasite was represented by a series of small blue grains between which no marking threads could be distinguished.

3. *The Quartan Parasite.*—In only four cases of the

series were organisms found which probably belonged to the quartan type. These cases responded promptly to quinine. The histories were not of typical quartan seizures, and, as the paroxysms were not repeated, the diagnosis could not rest on the clinical records. In these cases the organisms were highly refractive and slowly amoeboid in the fresh condition; the cells were shrunken and the pigment unusually coarse in stained specimens. No chills were observed, and no rosettes seen in the blood. The cases were therefore classified as those showing no organism that could be positively identified.

4. *Atypical Organisms.*—In most of the cases classified as showing no parasites that could be positively identified, atypical, intracellular, pigmented bodies were found.

Such bodies are to be distinguished from (1) bluish staining masses, often seen in the red cells of any secondary anemia; and (2) from blue-stained foreign bodies lying in or on the red cells, which often simulate the malarial organism. Aside from these possible sources of error, in well-established cases of malaria after much quinine has been taken, one frequently meets with shrunken atypical "quinine organisms" usually containing one or more pigment grains. They are usually irregularly spherical in outline, and the infected cell should always show some alteration in size, form, or hemoglobin.

While such bodies do not constitute evidence on which the positive diagnosis of malaria may be based, the frequency of their occurrence in undoubted cases of malaria at Montauk leads the writer to believe that their significance is greater than the conservative blood-analyst would naturally admit.

Vacuolated, pigmented and non-pigmented, extra cellular bodies were seen in many cases. This group does not include the adult tertian parasite, which in the fresh condition usually appears to be free from the cellular remnant almost invariably demonstrable by staining, nor the large sterile homogeneous forms showing pigment in vibratory motion.

In the fresh condition the appearance of the cystic extracellular bodies strongly suggests an origin from malarial parasites.

In rare instances sluggish amoeboid motion may be observed, in which case their malarial origin can not safely be denied, although pigmented leucocytes sometimes show amoeboid motion.

On the other hand, cystic leucocytes are very common in malaria. They were noted in every case examined in the fresh condition at Montauk. When these cystic leucocytes contain pigment, as they not infrequently do, it appears to the writer impossible to distinguish them from the bodies described by some as extracellular forms of the malarial parasite.

In stained specimens none of the cystic leucocytes were seen in the present cases, but in the entire series the writer met with no instance of this type which

could be regarded as extracellular forms of malarial parasites. All suspicious vacuolated, pigmented, extracellular bodies gave evidence of their origin from leucocytes, and the conclusion was reached that in the absence of typical amoeboid motion, or vibratory motion of pigment, the identification of these bodies is extremely hazardous, and that the diagnosis of malarial parasites should not be based on their presence alone.

Pigmented leucocytes were noted in a large proportion of the specimens examined, and proved to be one of the most striking characters of the blood in nearly all forms of malaria. The pigmented leucocytes were usually of the large mononuclear variety. Some of them had englobed not only pigment, but the bodies of parasites, and were themselves often cystic. In one case (67) very large macrophages, thirty-five to forty micromillimetres in diameter, were found in the circulation.

The pigment was usually coarse and brownish-yellow in the aëstivo-autumnal cases, and slightly finer and darker in the tertian cases. In old cases all pigment appears to assume a much darker color. It occurs in small rods or grains, either scattered through the body of the cell or gathered in masses of considerable size. In typical form these leucocytes were unmistakable, but when scanty in number and containing only one or more small black grains, they had to be distinguished with care from leucocytes contaminated during the preparation of the specimen.

Pigmented leucocytes were most abundant in well-established cases of aëstivo-autumnal fever. The largest numbers were seen in a fatal case of double infection (67). Their recognition proved of great diagnostic value in (1) *chronic malarial fever*, when they were often found after all trace of parasites had disappeared, and (2) in cinchonized cases of more acute fever, in which plasmodia could not be found. In the later stages of aëstivo-autumnal fever pigmented leucocytes were many times found in five to ten minutes, while the discovery of a crescent required an hour or more.

Free pigment, probably of malarial origin, was seen in many cases, but never in the absence of pigmented leucocytes.

Occasionally red cells were found to contain pigment similar to that seen in the leucocytes, but no trace of a parasite.

The Occurrence of the Plasmodium in the Circulation.—The plasmodium was found in the blood in every case in which the blood was secured within eighteen hours after the chill. In only one case (156) was the organism not found twenty-four hours after the chill. Scarcely half of the cases had taken heavy doses of quinine, many of them for several days before coming under observation. In the great majority of the cinchonized cases of acute aëstivo-autumnal fever organisms were found if the blood was examined within a week after the beginning of the paroxysm, while crescents frequently

persist for ten, or sometimes for fourteen days, or longer.

As previously stated, there was a period noted in several cases between the second and fourth days, when large doses of quinine had completely rid the blood of the signet-ring forms, and, in the absence of crescents, the examination proved negative.

On the other hand, a prolonged search was often required before the organisms could be detected. In three cases examined during the chill, thirty-five, forty-five, and fifty minutes were required before a single signet-ring form could be detected, and in nine other cases only crescents could be found (fifteen minutes' search) during the chill.

In four cases examined twelve to eighteen hours after the chill, the discovery in one of a single tertian parasite required thirty minutes, and in three, sixty and seventy minutes were required for the detection of one signet-ring form.

In one case examined twenty-four hours after the chill one signet-ring form was found after a search of two hours and ten minutes. In another case (456) two hours' search was unsuccessful, although atypical pigmented intracellular bodies and pigmented leucocytes were seen. A second specimen could not be secured.

The conclusion is drawn from these data that the parasite can always be found if the blood is examined with care and persistence within twenty-four hours after the beginning of the chill, although quinine may have been administered in large doses.

In thirty cases of *remittent malarial fever*, selected as showing fairly continuous pyrexia, rings alone were found in eight; crescents alone in eleven; both rings and crescents in one; tertian parasites alone in one; double infection in one; and no distinct organisms in eight.

In many other cases a continuous pyrexia lasting three to seven days was noted, but these cases did not seem to fall properly within the class of remittent malarial fever.

In chronic cases, during febrile periods, organisms were usually found in the blood, but they were often missed during afebrile periods. In one case (507), exhibiting an irregular fever, crescents were found four weeks after the last chill, quinine having been constantly administered. In another case (310) young crescents were found three weeks after the last chill, in spite of the use of quinine. It is probable that mild seizures had been overlooked by these patients.

Typhoid Fever and Malaria.—In sixty-nine cases giving a distinct history of recent malarial fever and exhibiting similar evidence in the blood, in the form of severe anaemia, pigmented leucocytes, often atypical pigmented intracellular bodies, and in some cases a few plasmodia, the question of a double infection with typhoid fever and malaria had to be considered.

Of these, forty were reported as cases of *typhoid fever in anæmic and malarial subjects*. In some of

these cases the disease began with one or more short rigors repeated on successive days, after which the disease progressed with the usual symptoms of typhoid fever. In one such instance (791) tertian parasites were found during the first few days and before typhoid fever was suspected, but they disappeared rapidly under quinine, and were not again seen. The patient died from peritonitis in the fourth week.

In another case (514) the usual history of Cuban malaria was interrupted by the development of typhoid fever with all essential symptoms. Plasmodia could not be found in the blood, but in the second week of convalescence tertian chills and fever developed, and tertian parasites were found in the blood.

In a third case (683) the history indicated the slow onset of typhoid fever in Cuba, which was safely withstood without quinine, but in the second week of convalescence tertian chills and fever supervened and tertian parasites were found in the blood.

There were other cases (1, 3, 51, 115, etc.) illustrating the same behavior of the malarial infection during the course of typhoid fever.

Further evidence of the usual incompatibility of malarial and typhoid fevers was furnished by the two fatal cases of typhoid fever in malarious subjects that came to autopsy (523, 683). There no parasites could be found in the blood during life, but in smears from the spleen and marrow diligent search revealed the presence of a very few rings and crescents, with much old malarial pigment.

The reason why the blood was examined in a hundred and fifty-nine cases of typhoid fever was the intermittent character of the fever, which was exhibited in patients both with and without malarial antecedents. *In no case of undoubted and established typhoid fever were malarial parasites found in the blood in connection with any of these sudden rises of temperature, but only at the onset of the disease or during the convalescence.*

On the other hand, many patients whose blood contained numerous parasites were seen in the "typhoid state," but there were always some essential symptoms lacking to confirm the diagnosis of typhoid fever, while the subsequent course of the disease, where observed, demonstrated the purely malarial character of the fever.

These patients might suffer from epistaxis, hæmatemesis, bloody stools, tympanites, a few rose spots, though oftener herpes, diarrhoea, and delirium, and in some a partial Widal's reaction was obtained. But the intestinal symptoms were inconstant or referable to dysentery or simple diarrhoea, from which many of the malarial cases suffered, and these patients never showed subulnus or cracked tongues, and they did not die, or, if they did, dysentery and malaria were demonstrated at or before the autopsy.

In another group of twenty nine cases, the absence

of any large number of parasites, and the presence of typhoid symptoms, left a reasonable doubt regarding the diagnosis.

These cases seemed almost certainly malarial, on account of the previous history, the facies, the anemia, and usually the sudden recovery at the turn of the disease, while in seven of them a few parasites were found in the blood.

On the other hand, the suspicion of typhoid fever was raised by the continued fever, abdominal symptoms, and general typhoidal state, although symptoms of typhoid fever were not present in distinct and convincing form. A moderate reaction with Widal's test was sometimes obtained in these cases, but this evidence failed to be convincing after sharp reactions had occurred in a case of dysentery (269) and in a cinchonized case of pernicious malaria (328).

It is possible that some of these patients suffered from both active malaria and typhoid fever, but there were no positive indications that the latter infection was present. In the cases that came to autopsy there was never any doubt of the nature of the disease. It was either typhoid fever or malaria, but never both, although microscopical evidence of dormant malarial infection was found in at least two cases of typhoid fever.

In short, in spite of very painstaking effort, the attempt to find a case of typhoid fever and active malaria progressing simultaneously was unsuccessful.

From the study of this group of cases it is concluded:

1. That typhoid fever is to a large extent incompatible with active malarial fever, and that during the course of the former the latter infection is usually suppressed.

2. That the presence of old malarial infection may alter the course of typhoid fever through the anemia, but that active sporulation of the malarial parasite very rarely occurs during the course of established typhoid fever.

3. On the other hand, since malarial paroxysms often reappear during convalescence, a scanty growth of the parasite must often persist during the course of typhoid fever, and it is possible that some of the irregularities of temperature observed in these cases are referable to this partly suppressed growth.

4. That the anatomical evidence of a post-mortem examination is much needed to demonstrate the existence of typhoid fever in cases showing active malarial paroxysms.

Measles and Malaria.—During convalescence from measles, symptoms of malaria developed in two cases, and parasites were found in the blood, crescents in one case and tertian organisms in the other.

The eruption in these cases had been characteristic, but the course of the disease had not apparently been altered by the activity of the malarial infection.

THE ELECTRIC-ARC BATH.

A CLINICAL REPORT.

By MARGARET A. CLEAVES, M.D.

(Concluded from page 122.)

CASE I. *Acute Phthisis*.—E. M., a man, aged twenty-eight years; married; carpenter. January 23, 1897.

Patient presented himself because of cough, with pain in chest, following a malarial attack last summer. Now has constant cough, muco-purulent expectoration, night sweats, cachexia.

Inspection: Skin pale and white; emaciated; clavicle and ribs conspicuous; retraction of chest walls, with impairment of motion in infraclavicular spaces; heart beat in normal position, accelerated.

Palpation: Vocal fremitus increased at right apex.

Percussion: Marked dullness over right apex, extending to fifth interspace.

Auscultation: Broncho-vesicular breathing, sibilant and subcrepitant râles over right apex. Increase of vocal sounds. On left side very harsh inspiration and broncho-vesicular expiration. Pulse, 100; temperature, 100.2°; weight, a hundred and twenty-one pounds and three quarters.

Treatment: Electric-arc bath; exposure from twenty to thirty minutes; temperature of bath, 90° F. Five treatments given, extending over a period of two weeks. At second visit "more life and energy and felt like getting around," before "felt like sitting about"; appetite better; cough diminished. At time of the third visit, further diminution in cough; sputum less purulent. At the fourth visit cough was much diminished, strength increased, a sense of well-being.

Improvement maintained; no night sweats while under care, save night following first treatment; improved color; gain in weight, two pounds and a half. The patient through whom he came to the clinic reported, two weeks later, continued improvement, and that he had gone to work again. Subsequent history not known. Two specimens of sputum were secured and examined, but the *Bacillus tuberculosis* was not found. Examination not regarded as conclusive.

CASE II. *Chronic Phthisis*.—J. B., a man, aged forty years; married; plate printer. December 28, 1897.

Has worked in a plating factory (bronze) for eight years. Onset sudden; began to cough and expectorate muco-purulent matter November 1, 1891. Condition has persisted for past six years; morning cough and almost daily expectoration. For past seven months dyspnoea on exertion; evening temperature. Under medical care for five years; thinks he is no worse than one year ago, save increased dyspnoea. Has had three tubercular ulcers (laryngeal); two disappeared under treatment, third remains. No history of consumption in the family.

Physical Examination.—Inspection: Emaciated; waxy skin; marked dyspnoea; incessant cough; impairment of motion in infraclavicular spaces; clavicles conspicuous; heart beat accelerated; respirations more frequent than normal.

Palpation: Skin warm and dry; increased vocal fremitus both upper lobes, especially right.

Percussion: Marked dullness upper lobe, right, less marked on left.

Auscultation: Increased vocal fremitus both upper

lobes; cavernous breathing on right; subcrepitant râles right lower lobe posteriorly; friction râle on left, low down.

Examination of sputum: *Bacillus tuberculosis* found.

Treatment: Electric-arc bath; exposure thirty-five minutes; temperature, 90° F.

Twenty treatments given, extending over a period of seven weeks and a half. At first visit, incessant cough from time of entering clinic room up to going into bath. Just before conclusion of bath marked moisture of the palms, hands, and forehead observed.

Sensation of bath pleasant; coughed but once during its continuance, and not but once for twenty-five minutes afterward. Two days later, at second visit, stated that he had coughed less since treatment than during the same time for two months previous.

At conclusion of second treatment hands and forehead moist as before; no cough; freer and easier respiration during bath.

At the third visit reported less dyspnoea. At the fourth visit, January 6, 1898, no cough night of previous treatment, January 4th; once night of 5th; not at all during day of 6th. Rate of respiration diminished from 40 before first treatment to 30.

At the fifth visit, eleven days after coming under care, dyspnoea diminished; able to walk several blocks without getting out of breath.

Expectoration of a saltish taste instead of sweetish as before, more nearly normal in color, contained less purulent matter.

At the sixth visit, two weeks from beginning of treatment, had an irritative cough, with discharge from posterior nares. Walked ten blocks two days previously; dyspnoea slight; expectoration decreased; color of skin improved; sleeping better; no cough while at clinic, an hour and a half; laryngeal ulcer healed; throat much less anæmic. Throat examined January 10th at Throat Clinic, New York Polyclinic, healing of ulcer also noted.

At the first six visits the electric-arc bath alone was used.

Beginning on the seventh, and for the remaining fourteen treatments it was followed by Franklinian current, positive insulation, convective discharge with crown electrode, ten minutes, and with brush electrode to entire general surface (nutritional) localized to chest walls front and back (lungs), five minutes.

During seventh bath no cough. Three and a half weeks after coming under care increased strength; brighter facies; better color; eyes not so preternaturally bright. Improvement continued, characterized by diminished cough, expectoration, improved appetite and sleep. On January 18th nasal and throat examination revealed hypertrophic rhinitis and pharyngitis. For this two applications of intranasal cupric electrolysis were made at intervals of nine days. About the 1st of February for a day or two appetite not good; cough slightly increased. Sputum examined on admission to clinic two weeks later, and again at end of four weeks; *Bacillus tuberculosis* found in every instance; fewer in the field at last examination.

At no time while under treatment did patient have special nursing and exceptionally sufficiently nourishing food. This was especially true during the month of February. February 23d admission was obtained to St. Luke's Hospital in order that he might have care and nutritious food during the trying weather of the spring months. For the first eleven days gained five pounds,

which he lost in the next ten days. Three weeks after entering hospital complained of sore throat. Examination revealed two tubercular ulcers on laryngeal cartilages. In the hospital until April 1st; unable to swallow food; discharged April 1, 1898. Returned to clinic April 7, 1898. Emaciated; extreme pallor; dyspnea, and exhaustion. No physical examination made because of the patient's great exhaustion, but the following treatment was given: Frankline current, positive insulation, convective discharge, chain in hands, with crown electrode, fifteen minutes, and with brush electrode to the entire general surface (nutritional), localized to the chest walls, front and back (lungs), and over laryngeal region (ulcers), ten minutes.

Patient felt brighter and stronger after treatment, dyspnea lessened, improved circulation, return of color to face, able to get down stairs more comfortably. The query naturally rises, Might not the improvement established have maintained itself if the patient could have had continued treatment while in the hospital, where food and care were provided? It is impossible to answer the question now, but it seems reasonable to believe that under proper conditions the continuance of the treatment would have led to better and more permanent results. This patient was living a month since (about August 7th) and up and about. Owing to change of residence can not ascertain his condition at this writing. For several years he had been given creosote, nor was it discontinued when he came under care, on account of his desperate condition. The relief obtained, however, was coincident with the establishment of his treatment by means of the electric-arc bath, and progressive under its use.

CASE III. Acute Phthisis.—B. B., a woman, aged thirty-five years, single; seamstress. January 4, 1898.

Patient had *la grippe* five or six years ago; pleurisy four years ago, and since then when she takes cold suffers pain in breathing, left side. In May, 1897, contracted a severe cold; tired; pains all over body; knees, ankles, and hands stiff; in hospital eight days; improved. Has not been fully well since; now pain and stiffness in shoulders, arms, fingers, and feet; badly nourished; constipated. For malnutrition and rheumatism the following treatment was given: Frankline current, negative insulation, disruptive discharge, sparks long, clean, and percussive to entire general surface (nutritional), localized to affected joints (pain and disability), and to lumbar and sacral plexuses, hepatic area and abdominal walls (constipation). Eighteen treatments were given, extending over a period of four months, establishing marked nutritional gain, with great relief from pain and stiffness and constipation.

Patient discontinued regular attendance April 2, 1898.

On April 16, 1898, returned, complaining of sore feeling through chest, with mucopurulent expectoration. Usual treatment given, but could not remain for physical examination.

May 3, 1898.—Physical examination: Congestion of right lower lobe, difficult breathing; hard, dry cough, scant expectoration.

Treatment: Electric arc bath, exposure thirty minutes; temperature of bath, 90° F. Nine treatments given, covering a period of five weeks. Followed by treatment respiration freer and easier; appearance brighter. May 5th sputum examined, *R. B. C.* 100,000, *W. B. C.* 10,000, *L.* 10,000. At the second visit looked much better, less worn, no sense of oppression in breathing, chest

treatment, cough looser. Physical examination made at time of fourth treatment showed sibilant and sonorous râles, and elicited the fact of moderate expectoration. After fifth treatment patient felt stronger; coughed less. Continued improvement characterized by increased strength; more energy; diminished cough and expectoration, freer respiration. Clinic closed June 11th for summer holidays, therefore further treatment could not be given. Arrangements were made to send patient to the country under the auspices of an association for the relief of working girls, the subjects of tubercular troubles. Overfatigue and exposure to night air incident upon her going for the necessary physical examination by the physician of the association brought on an exacerbation of her trouble, and she did not leave the city until July 30th. On August 16th reported by letter from Franklin County, New York, that she had gained three pounds and was much better. Case to be followed up.

CASE IV. Acute Phthisis.—M. E. L., married. Came for consultation March 31, 1898. Family history good; no consumption; patient had systematically overworked in the active care of a large business concern; general health poor for several years; less well for a year past.

In the spring of 1897 began to cough, lost strength and flesh. In the same summer took a sea voyage and was absent from his business several weeks. Nutrition improved and cough diminished during this time, but soon after his return took cold, cough returned with loss of flesh and strength and increasing nerve irritability. In September he was seen by his physician and examined also by Dr. Delafield. Trouble was found at the apex of the right lung and bacilli in the sputum. Dr. Delafield told him he must give up his business and go elsewhere in order that he might be under suitable climatic conditions. The patient was very much averse to this, and decided that rather than give up his business interests and go away he would work as long as he could in order that he might provide in the best possible manner for his family and accept the inevitable when it came.

He did nothing during the winter and early spring, save to take cod-liver oil and hypophosphites. At the time he came under care, March 31, 1898, he was a good deal worn; nervously irritable; had lost, and was still losing flesh; coughed a good deal, especially in the morning and at night; wakened by cough between four and five in the morning; expectoration mucopurulent; appetite poor and sleep broken.

Physical Examination.—Inspection: Patient fairly well nourished. Clavicles and ribs somewhat conspicuous.

Palpation: No change in tactile fremitus.

Percussion: Slight dullness over upper lobe on right, front, and back. Note normal on left, front, and back.

Auscultation: Subapical râles, dry, and below clavicle on right over area of upper lobe. None, and breathing slightly bronchial; none heard from left.

Examination of sputum: *R. B. C.* 100,000, *W. B. C.* 10,000, *L.* 10,000.

In answer to his question as to whether or not he could hold on for long, the fact of value of treatment, whether natural or artificial, and the treatment was decided upon. He was advised to continue in work as long as he could, and the improvement of his condition was to be followed up. The improvement of his condition was followed up. He decided to place himself under my care, and to

ment was instituted on the same day. For the first fourteen days treatments were given daily, with the exception of the intervening Sundays.

Treatment consisted of the electric-arc bath; temperature of bath, 90° F., exposure varying from thirty minutes to an hour. There was an immediate diminution of the cough, with gradually diminishing expectoration. Improved appetite and sleep, and marked lessening of nerve irritability. At the end of the first week of treatment the patient had gained three pounds; cough was markedly diminished; sleep and appetite improved. Improvement continued, and two weeks from the day he came under care physical examination was negative, save for a slight increase of vocal resonance at the apex of the right lung. In an examination of the sputum two weeks and three days from the time of instituting treatment no bacilli were found. The gain at that time in weight was five pounds. Throughout the rest of April and during May almost daily treatments were given, Sundays excepted, and an occasional week day. In one instance only was there an exposure of an hour, and that at the request of the patient, to whom the bath was most grateful, but it was followed by unusually profuse perspiration with slight exhaustion. After that time fifty minutes was not exceeded, while the average time was forty-five minutes.

During the month of June and the first week of July an average of from three to four treatments a week were given. At the beginning of the fourth week he was directed to secure a third specimen of sputum for examination, but at no time, either in the night or morning, was he able to secure anything, though he carried a bottle in his pocket for this purpose for the following two weeks.

There was absolutely no cough or expectoration. Improvement in appetite and sleep continued, with a further increase in weight, entire disappearance of nerve irritability, and withal a general sense of well-being.

During the month of June his business necessitated his going into a new building, which had not fully dried out, and as a result he developed malarial symptoms. He had at different times in his life suffered from chronic malaria. At that time he was given an anti-periodic, which was the first and only medicine given him while under treatment. Cod-liver oil was not used, but as much cream was taken as he could digest.

In all sixty-six treatments were given, extending over a period of three months and ten days. In the second week of his treatment the electric-arc bath was omitted for three or four days, owing to an accident to one of the lamps which was not promptly repaired.

Following the arc-light bath the following was given: Franklinian current, positive insulation, convective discharge with the crown electrode, fifteen minutes, and with brush electrode to the entire general surface (nutritional), localized to chest walls front and back (lungs).

With the establishment of nutritional changes some three weeks after coming under care the disruptive discharge was used and the application made to the entire general surface. At the same time a hypertrophic rhinitis with hypertrophy of the posterior turbinated bodies was treated with cupric electrolysis.

The applications were made with a thin copper electrode having concavo-convex surfaces, by means of which an accurate localization of the oxychloride of copper was made directly over the turbinated bodies. Before instituting nasal treatment there was difficulty

in breathing, with profuse post-nasal dropping and constant hoarseness. These symptoms were of several years' standing. In addition to the nasal treatment a slow interruption of the induced current regulated to the patient's toleration was used by percutaneous applications to the throat—i. e., from side to side for five minutes, and from nape to larynx for five minutes, daily. As a result of nasal treatment nasal respiration became absolutely free, and post-nasal dropping stopped entirely.

To date there has been no return of these symptoms. The throat became very much stronger under the use of the induced current, with gradual disappearance of the hoarseness, which returned but once while under care, when, owing to a sudden change one late afternoon from the extreme heat prevailing, he took cold. He came to the office the following morning with an acute laryngitis, exceedingly hoarse, with almost a whispering voice. The usual treatment was given: Electric-arc bath, followed by convective discharge, and the application of the induced current to the throat.

He left the office at conclusion of treatment with practically a normal voice, and maintained his improvement.

His total gain in weight up to the end of the first week in July was eight pounds. He is a man of very slight build. He attended to his business every day, not losing an hour, save the hour spent in the office for the purpose of treatment. A note on the 6th of July, stating his inability to keep an appointment, ends with the remark "feeling fine." On the 9th of July, writing in reference to being away for his vacation, he stated that he was very well.

This patient has been given to understand that the maintenance of his improvement depends very largely upon himself, that every attention must be paid to all matters of hygiene, and that he must have outdoor exercise and sunshine. Realizing fully the nature of tuberculosis, it follows that if at any time his nutrition falls below par the bacilli are apt to become active and the trouble develop anew.

The positive results obtained in this case as well as the improvement obtained in cases of much longer standing are, to say the least, suggestive.*

CASE V. *Acute Phthisis*.—M. T., a woman, aged twenty-eight years, single; importer. July 9, 1898.

Father died of pneumonia; mother has chronic malaria; one brother died at age of six with "brain trouble." Patient not strong and always nervous as a child. Menstruated at age of twelve, usually pain for twenty-four hours before flow, duration four days, amount normal. Has occupied her present position for eight or nine years, and has overworked; meals irregular; for past four years much mental worry. Life indoors most of the time. Four years ago last February began to go to Paris twice a year to buy goods, since that time less strong; for three years tired all the time; unable to get rested; very nervous and has lost flesh during last two years. Last February took cold, nose and throat first, finally lungs.

Since then has had a cough, especially on retiring and rising; at intervals muco-purulent expectoration. Every two weeks since has had an attack of coryza with incessant sneezing and nasal discharge; malaise and great fatigue. At time of coming under care, morning and evening cough, worse in morning, wakens her, mu-

* November 25, 1898, the patient remains well.

cous expectoration, at times muco-purulent. Bowels constipated, micturition frequent. July 13, 1898, examination of sputum and *Bacillus tuberculosis* found.

Physical Examination.—Inspection: Patient poorly nourished; retraction of chest walls above and below clavicles, especially on right; skin inactive, pigmented in defined areas over sternum.

Palpation: Vocal tactile fremitus normal.

Percussion: Percussion note, anteriorly and posteriorly over upper lobe of right lung is of higher pitch and of shorter duration than normal. Note over left chest normal.

Auscultation: Vocal resonance increased over upper lobe on right subcrepitant râles below right clavicle; diminished breathing. Left side anteriorly sounds normal; posteriorly infrascapular region loud sonorous râles.

July 25, 1898.—Sputum examined and *Bacillus tuberculosis* found.

Treatment: Electric-arc bath; exposure twenty minutes to an hour. The shorter exposure was given on the hottest days. Free perspiration always established with improved color and rested appearance. At the end of the first five days cough markedly diminished both night and morning, expectoration decreased. For the first eight days treatment given daily except on Sunday; during the two weeks following treatment was administered daily with one exception, while the last week but three treatments were given.

August 5, 1898.—Physical examination: Skin of better color, less dry and harsh; respiration freer; volume increased.

Subcrepitant râles: no sibilant or sonorous râles. Percussion note improved. Sputum examined and *Bacillus tuberculosis* found.

At intervals of five days three applications of cupric electrolysis made to hypertrophied turbinated body, inferior left, five milliamperes, three minutes each. At the end of two weeks, in spite of the heat of the summer weather and continued application to business, there was a gain of one pound; improved appetite and sleep; general sense of well-being; no cough at night, rarely in the morning; scarcely any expectoration, save from the throat. Menstruations established August 1st, free from pain, very comfortable. Is to sail for Europe tomorrow, August 6th, to be gone five weeks. The following was given to take during her absence as a digestive tonic:

Fluid extract of *enseada sagrada* . . . 3 drachms;

Dilute nitrohydrochloric acid . . . 4 "

Elixir of calsaya bark 4 ounces.

M. Sig.: One tea-spoonful half an hour before meals as needed to keep bowels open.

Also—

Arsenous acid $\frac{1}{8}$ grain,

Iron powder $\frac{1}{2}$ grain, each.

Tablets, 100. Sig.: One three times a day, just after meals.

She is to return for examination the last of September, and will continue under observation.

CASE VI. J. G., male, aged twenty years; shipper clerk. August 19, 1898. Father dead; mother living and well; one sister, one brother, both well. For the last two or three years not well, chronic malaria. Began to run down in April last, and had a severe hemorrhage, pulmonary, at that time. Went to the country, about until July 14th. No hemorrhage during absence. Made some gain. Since return has steadily lost weight,

troublesome cough, with expectoration; sense of malaise; poor appetite. In July had a very severe hemorrhage, lost a good deal of blood from which he has not recovered. On July 31st consulted Dr. C. O. Maisch, instructor in diseases of children, New York Post-graduate Medical School and Hospital, who reports the following:

"Slight dullness over left apex, anterior more marked; accentuated breathing. Vocal fremitus slightly increased, no râles. Right lung over apex a few sibilant râles, respiration over both lungs very much restricted. Retraction of intercostals and some dyspnoea always present. Expectoration moderate, cough not very troublesome. Haemoptysis; anorexia; malaise weakness; emaciation progressive. Sputum contains a very few tubercle bacilli. Temperature, 100.2°; pulse, 110.

"August 12th.—Physical examination: Over left apex dullness to within an inch of inferior angle of scapula, and over this area there is marked increase of vocal fremitus; bronchial and tubercular breathing; crepitant and subcrepitant râles; moist mucous râles over the entire surface indicated. Right lung unaffected. General condition much worse. Temperature, 101.5°; pulse, 120; cough troublesome and expectoration considerable.

"August 20th.—Patient in same condition; complains a great deal of weakness."

This patient was referred to the writer for treatment August 19, 1898. Physical examination was not made nor treatment instituted until August 20th. At that time patient presented appearance of a very ill person, loss of flesh, great difficulty in breathing, rise of temperature, evening and morning cough most marked, occasionally during day, moderate expectoration, poor appetite, regular bowels, malaise, great weakness, and walked with difficulty even a few steps.

Physical Examination.—Inspection: Patient much emaciated, anæmic; chest walls retracted; left chest flattened, with impaired motion.

Palpation: Marked increase of vocal tactile fremitus over left chest anteriorly.

Percussion: Marked dullness over upper half left lung anteriorly and posteriorly.

Auscultation: Crepitant and subcrepitant râles over area of dullness on left; vocal fremitus markedly increased; harsh breathing. Right side normal.

Patient very weak and obliged to sit several times during the examination.

Treatment: Electric-arc bath; exposure twenty to thirty minutes; temperature, 90° F.; followed by Franklinic current, positive insulation, convective discharge with the crown electrode for fifteen minutes, and with brush electrode to entire general surface (nutritional) localized to chest walls front and back (lungs) for five minutes. Afterward sat upon the platform for five to ten minutes daily with ground connection removed and discharging rods within sparking distance of one another. During this time directed to breathe deeply and steadily of the nasal apparatus.

Daily treatments given up to August 27th, excepting the intervening Sunday, and gave a two minutes exposure later for 1000 amperes. From the beginning of treatment there was a gradual improvement of dyspnoea, increasing respiratory capacity, and a decrease in cough, with, as a rule, better coloration.

On August 25th appetite improved, much better forces brighter, respiration freer, and color very in the morning.

ing, and less than before; taking sufficient food, but without special appetite; lowered temperature and diminished pulse rate; able to walk five or six blocks without much effort. On the 26th and 27th had rather a sharp attack of diarrhoea which caused considerable weakness. From August 19th the weather was excessively hot, with great humidity, and as patient's home was a single room in a tenement house in the most crowded portion of the city, he was unable to get much rest at night.

On August 27th referred back to Dr. Maisch for examination with the following result: Temperature, 99° F.; pulse, 115; general condition of patient improved; dyspnoea less troublesome (very much); cough less. Lungs: Left apex, dullness as before, has not extended. Rhonchi seemed fewer in number, and would indicate that liquefaction was not so great as at last examination. Right lung not affected. Moderate diarrhoea. To patient, physician stated "you are very much better." Treatment: August 29th as before. Slight diarrhoea; coughing but little, and in morning only; raising less than before. In answer to an inquiry as to why the patient did not return for treatment, the following letter is quoted:

223-225 EAST ONE HUNDRED AND SEVENTY-SIXTH STREET,
NEW YORK CITY, September 7, 1893.

DEAR DR. CLEAVES: Yours of the 2d inst. in reference to J. G. received. I had heard nothing of him, and so looked him up yesterday at his home in Baxter Street. He has been in bed some days. I found him with temperature 104° F., pulse 120, and in pretty bad condition. He has an acute pleurisy on the left side anteriorly. The physical signs in the chest have not changed since I saw him, except that he has developed a diffuse bronchitis, involving both sides. His general condition is worse; his surroundings are bad, and the hygienic conditions hopeless. He has had no hæmorrhage. Should he get up again he will come to you.

Yours,

C. O. M.

CASE VII. *Eczema Cruris*.—A. M., a woman, aged twenty-nine years, single; dressmaker. February 18, 1896.

Presented herself because of spot on anterior surface of right leg. One year since fell and scratched her leg below the knee. Spot became red, infiltrated, itched moderately with tendency to moisture, stocking adherent; later crusts appeared on the surface.

Physical Examination.—A patch size of palm of hand below patella, color dull red; covered with crusts and exuding moisture; tissues underneath thickened and swollen.

Treatment: Continuous current, active electrode, six square inches in area over eczematous surface negative; indifferent electrode right foot in normal saline solution. Temperature, 100° F., five milliamperes, ten minutes.

Four applications were made, extending over a period of ten days. After second treatment marked hyperæmia over upper part of patch; tissues softer, with partial loss of crusts. After third treatment several islets of healthy skin visible, fewer crusts; improved circulation. Because of general malnutrition treatment changed from local application of the continuous current to general nutritional treatment as follows: Electric-arc bath; exposure thirty minutes; temperature of bath, 90° F.

Two treatments extending over a period of sixteen days. Not able to come for further treatment because of a severe cold contracted from exposure going to and from her work. In May reported through a friend that the patch of eczema had entirely disappeared. No drugs given. From clinical experience with other cases of eczema treated solely by the continuous current the opinion is justified that the prompt and complete disappearance of the eczematous spot was due to the action of the electric arc. The light was focused directly on the spot of eczema.

CASE VIII. *Subacute Bronchitis*.—F. W., a girl, aged three years. December 3, 1896.

At the age of sixteen months patient had pneumonia, at two years tonsillitis, and eight months subsequently malaria, intermittent type. Two weeks prior to admission contracted a severe cold, characterized by febrile disturbance, loud breathing, moaning in sleep, pain through chest and cough at night.

Physical Examination.—Subcrepitant râles over chest anteriorly and posteriorly; crepitant râles in inferior clavicular region left; sibilant râles right.

Treatment: Electric-arc bath; exposure twenty minutes; temperature of bath, 90° F.

Eight treatments given, covering a period of six weeks and a half. Pulse and temperature records taken before and after treatment showed that the pulse, markedly irregular before treatment, became normal in character after the first three treatments. It was uniformly diminished in rate and of better volume. Upon leaving the bath the skin was always warm and moist and respiration freer.

At the fourth visit physical examination revealed the presence of large mucous râles, and the mother reported that the cough was looser. After the fourth treatment patient did not cough during the night. The congestion gradually disappeared, appetite and sleep improved, and respiration became normal. Patient always fell asleep in bath. Discharged recovered. No drugs given.

September 1, 1898.—No trouble since.

CASE IX. *Psoriasis Universalis*.—H. B., a woman, aged twenty-six years, single; nurse. April 10, 1895.

Referred from the New York Skin and Cancer Hospital.

Physical Examination.—General eruption over body, more marked on extensor surfaces of arms and legs; red papules covered here and there with silvery white scales; no discharge; conjunctiva and gums anæmic; depressed; case has proved an obstinate one, and has not yielded to classical treatment.

Treatment: Electric-arc bath; patient nude; exposure thirty minutes; temperature of bath, 90° F. Four treatments given, extending over a period of nine days. After first bath, circulation improved, skin warm and moist; patient felt warm and comfortable and looked rested.

At second visit improved appetite and sleep with general sense of well-being. After second treatment remarked that she "felt that she had been born again." Improvement continued, characterized by nutritional gain and clearing up of skin. Treatment suspended at end of nine days, as patient had to leave the city. Subsequently heard from through an interne of the New York Skin and Cancer Hospital, who reported that she was entirely well. No drugs given. In this case, as well as every other reported, the patient always looked rested and refreshed upon leaving the bath, skin moist and rosy, eyes bright.

IODOFORM AS AN INTERNAL REMEDY IN LUPUS ERYTHEMATOSUS.

By HENRY H. WHITEHOUSE, M.D.

AFTER all that has been said recently at dermatological gatherings, both here and abroad, upon the subject of lupus erythematosus and its treatment, there would appear to be little excuse for one to record his experience with an internal remedy in a single example of the disease. The result, however, was so striking in this instance that a plain recital of the facts as they were observed will at least be of some interest, and might, in the opinion of the author, lead to further investigations that would possibly be of value.

There is no disease in the entire domain of cutaneous medicine that is more rebellious or unsatisfactory to treat than lupus erythematosus; this, I believe, is generally conceded by all who have made a special study of this class of affections. If, therefore, any drug is found to be capable of curing, or of contributing even to the cure of, one case of the disease, whether or not its effects can be explained on pathological or other grounds, the fact is certainly worth recording.

The case itself was a very unusual one, not only because it presented a great number of small patches of the disease, but in consequence, also, of the peculiar and extensive distribution of the diseased areas. For these reasons, it is thought that the following brief history may not be without interest:

The patient, an unmarried woman, fifty-two years of age, has always enjoyed the best of health. There is no history of tuberculosis in any branch of the family; on the contrary, all her people are rugged and long-lived, both her parents having passed the age of ninety.

The disease began three years ago on the scalp, which has been the seat of active lesions ever since. Soon after the eruption appeared she contracted a severe cold and applied capsicum plasters to the upper part of the chest, front and back, in the median line. When these were removed, the skin beneath was greatly irritated, and there quickly developed upon it lesions similar to those upon the scalp, which remained several months and disappeared. A year later, however, the disease developed again in these localities, and has remained to the present time, a period of two years.

Simultaneously with the recurrence upon the chest and back, a few small patches appeared on the external ear and behind it, on the sides of the neck near the angle of the jaw, and one patch on the bridge of the nose. The backs of the hands and the forearms became affected about the same time, and two or three lesions formed on the inner side of the left knee; these latter disappeared in a month or two, their sites now being marked by superficial scars. Those on the forearms were very numerous at one time, as evidenced by the many small atrophic scars scattered over the surface; one active patch, existent now on the right forearm, has existed two years.

During the past ten months the disease has progressed very rapidly upon the face, and at present its gradual extension from week to week is readily noticeable.

The eruption is everywhere typical of lupus erythematosus, of a superficial type, and is markedly symmetrical in distribution. There are a great number of disfiguring, red, scaly patches upon the face, none larger than a five-cent piece, and many of them much smaller; there are no diffuse areas. Active lesions of the same character are found upon the scalp, together with small areas of alopecia resulting from earlier disease. Those on the chest and back and behind the ears show beginning atrophy in the centre. On the upper extremity the eruption is confined to the backs of the hands and the extensors of the forearms. The patient complains of almost intolerable itching.

The case, therefore, was one of disseminated lupus erythematosus of the superficial, discoid variety. In spite of its superficial character, however, for a year before she came under my observation she had been continuously treated by competent men, without any benefit; on the contrary, as before remarked, new lesions were developing all the time.

Treatment was begun March 1, 1898, with a lotion commonly known as "lotio alba," to four ounces of which a drachm of precipitated sulphur was added. This is a lotion that is used extensively in the treatment of acne, but I have used it also in lupus erythematosus with very good results. It was in just such cases—namely, the superficial type of lupus erythematosus—that Duhring* some years ago advocated the use of this particular remedy, in connection with which he cited several cases that were greatly benefited by it. The formula generally employed is sulphate of zinc and sulphide of potassium, each one drachm; water, four ounces. For two months and a half—that is, until May 17th—she used this remedy, with the addition of the sulphur, without the least benefit.

In the meantime I had presented her to the New York Dermatological Society as an unusual example of the disease, and the diagnosis was concurred in by all the members present.†

At the suggestion of Dr. A. R. Robinson, made at the meeting, she was given, on May 17th, a one-grain pill of iodoform after each meal, continuing at the same time the use of the lotion. In a few days the lesions began to tingle and burn, and became very much more pronounced. At the end of a week they were decidedly inflammatory, but the treatment was persevered in. After two weeks' treatment her condition was very much worse, the lesions everywhere presenting a very angry appearance, but as there were no general bad effects the remedy was continued in the same dosage. At the end of the third week the redness and inflammation began to subside, so that in four weeks from the time she commenced to take the pills all the tenderness, burning, and itching had disappeared, and the lesions were fast becoming

From this time improvement was uninterrupted, and

* *Ph. Med. J. N. S.*, November 19, 1888.

† *Journal of Cutaneous Medicine and Surgery*, December, vol. XXIV, p. 51.

in three months from the beginning of the internal treatment the eruption had entirely disappeared. The pills have been continued to the present time, a period altogether of seven months, though there has been no manifestation of the eruption for nearly four months.

The only reference that I can find in literature relating to the use of iodoform internally in lupus erythematosus is by Desnier,* who in 1880 cured two cases of the disease by means of it. They were both very rebellious cases, the lesions in one being seated upon the face, in the other upon the face and the backs of the hands; the latter case was cured before the end of the third month.

Without drawing any conclusions from the experience of one case, it would certainly appear that the iodoform contributed largely to the rapid improvement that took place soon after its administration and to the ultimate cure of the disease. Up to the time of its exhibition the case acted indifferently to the local measures employed, but showed a distinct reaction after it had been taken only a few days. It is unreasonable to suppose that the case was one of those which recover spontaneously, such recovery beginning only at this particular time; neither is it probable that the local application alone wrought this sudden change in the course of the disease after it had been used over two months with no effect.

Whether this particular lotion contributed at all to the final result can only be ascertained by further observations, in the course of which the drug should be tested alone in some cases and in conjunction with local treatment in others.

24 WEST THIRTY-SIXTH STREET.

THE VALUE OF AN ABSOLUTE NEGATIVE DIAGNOSIS IN CASES OF SUSPECTED FRACTURE.

By CHARLES LESTER LEONARD, A.M., M.D.,

PHILADELPHIA,
ASSISTANT INSTRUCTOR IN CLINICAL SURGERY, UNIVERSITY OF PENNSYLVANIA;
SKIAGRAPHER TO THE UNIVERSITY HOSPITAL.

In many cases of suspected fracture the ordinary symptoms may be absent on account of the relation of the fractured bone to others that are not fractured; on account of the line of fracture involving a joint or lying wholly within its capsule; because the case has not been seen sufficiently early to make it possible to elicit the pathognomonic symptoms of fracture, or in cases of impacted fracture.

In such cases it is often impossible to establish a diagnosis, and treatment has, therefore, to be carried out as if the more serious injury were present. As a consequence, a patient having a suspected fracture in-

volving the shoulder, the ankle, or the knee is compelled to forego the use of a limb for a period much longer than would be the case if an absolute negative diagnosis could be established.

No matter who the patient is, whether a society woman, a banker, a professional or a laboring man, the deprivation of the use of a limb, or the confinement in bed for at least five weeks longer than would be the case if an absolute negative diagnosis of fracture had been made, is a serious consideration.

Do we now possess the means of establishing an absolute diagnosis? I think we do. The Röntgen ray, if properly employed, is capable of making these absolute negative diagnoses, and its clinical value in this direction has been forcibly illustrated by the following cases:

A lady in going downstairs slipped and, in trying to save herself, brought a severe strain upon her right shoulder. The attending physician suspected a fracture of the neck of the scapula. An examination confirmed the suspicion, and the skiagraph demonstrated the correctness of the diagnosis. The patient, as a consequence, willingly acquiesced in the necessary treatment, which she would otherwise have refused to undergo.

In the case of a clergyman, a severe contusion, resulting from a trolley accident, made the use of the arm almost impossible. He did not consult me for some time after the accident, and then declined to take either for an examination. The skiagraph demonstrated the absence of fracture, and under appropriate treatment he rapidly regained the full use of the arm. He was thus saved four weeks of treatment that would have been necessary if the negative diagnosis had not been established and he had persisted in declining etherization.

The case of a dentist illustrates the value of an absolutely positive diagnosis. A chip from the margin of the glenoid fossa was easily detected, and the appropriate treatment resulted in perfect functional recovery.

A surgeon sustained a severe fall, and the symptoms were so marked that a serious injury was thought probable. The skiagraphic examination established a negative diagnosis, and the patient got out weeks sooner than he otherwise would.

A lady sustained a severe wrench of the ankle, and the experience she had had with severe sprains in her family led her to suggest a skiagraphic examination. This was readily acquiesced in by her attending physician and the consultant, as the parts were much swollen before she was seen, and a satisfactory examination could not be made. The skiagraph showed a fracture through the tip of the external malleolus, and the subsequent treatment for fracture resulted in complete functional recovery.

Another lady refrained from calling in her physician for some time after receiving an injury to her foot. The physician was unable to make an absolute diagnosis, and the consulting surgeon could not establish a negative diagnosis. The skiagraphic examination demonstrated the absence of fracture, and the patient was spared a treatment extending over from four to five weeks.

In the case of another lady, a fall on the elbow caused a contusion of the shoulder joint, while an apparent shortening led to the suspicion of impaction. The skiagraph demonstrated the absence of all osseous injury and shortened the treatment.

* *Annals de dermatologie et de syphiligraphie*, 1880, p. 628.

Numerous other instances might be cited in which injury to the various joints has been suspected, in which the absolute diagnosis by the Röntgen-ray method saved the patients serious loss of time, which would have been well spent if the absolute diagnosis of the absence of an osseous lesion could not have been established.

In addition to those lesions that involve the joints, the negative diagnosis which the Röntgen ray has made possible is most valuable in injuries of the phalanges, the metatarsal bones, and any other bones where the ligamentous attachment to another parallel bone masks the symptoms and makes the diagnosis difficult. This is also true of linear and splitting fractures and also of impacted fractures.

1930 CHESTNUT STREET.

STATIC ELECTRICITY FOR SPRAINS.

By CHARLES O. FILES, M. D.,

PORTLAND, MAINE,
FELLOW OF THE AMERICAN ELECTROTHERAPEUTIC ASSOCIATION

IN the discussion of sprains hitherto, directions have been given for four methods of treatment, following each other or combined, according to the judgment of the surgeon. These methods are rest, the application of cold, massage, and passive followed by active movements. Of all external applications my own experience favors the copious innation of very hot lard, or lard oil, used very frequently. The use of electrical massage is, however, so far superior to all other forms of treatment that we may safely discard their consideration except as adjuncts to the electricity.

A sprain is usually a laceration of capsular or lateral ligaments, with or without ruptured tendons, torn muscles, contusion or laceration of the synovial membrane. We know now, thoroughly, that repair of the injured tissues occurs as the result of internal rather than external forces. We use external applications for the purpose of stimulating the circulation, thus bringing an extra amount of blood to the parts and hastening its departure after it has accomplished its laudable object. Rest is also a useful ally, although we can now accomplish good results with less absolute rest than was formerly considered necessary. Electrical massage with the static roller meets all the indications for the successful treatment of these injuries more perfectly than all other means combined.

In proof of this statement very brief notes of two cases are here given, selected almost at random from a large number of similar histories in my private practice. The use of electricity in sprains had never occurred to me until an experience of more than fifteen years with hot and cold applications, bandaging, and rest had fully demonstrated the mutuality of these methods.

CASE I.—A policeman, weighing two hundred and fifty pounds, started to run toward a house from which cries of "murder" were coming. He stepped on some

thing which turned his ankle, but his impetus was so great that he was obliged to run twenty or thirty steps before he could stop. With the greatest difficulty, supported by a cane, he came to my office. On account of his great weight and the extreme swelling and pain, the indications were that he would be laid up a considerable time. A thick woolen shawl, folded many times, was carefully placed over the ankle and foot, and the static massage roller was used as strongly as he could bear it for fifteen minutes on the foot, ankle, and leg. The patient was seated on a stool on the floor, not on the insulated platform. The roller was attached by the chain to the positive pole of the static machine. This same treatment was followed for five days in succession. At the end of one week he resumed his duties as police officer.

CASE II.—A man, aged fifty, who weighs two hundred and thirty pounds, jumped over a fence five feet high. When he struck the ground on the other side of the fence one foot was turned over and the whole weight came down on the bent ankle. The pain was so intense that he fainted away. The accident happened in the immediate vicinity of my office, and the man was assisted there, and the same treatment was given as in the previous case. He attended to his business every day, and in two weeks could scarcely tell which ankle had suffered the injury.

There is no doubt but that in this class of cases the length of confinement to the house may be shortened very considerably by the use of electricity. For commercial travelers, often obliged to stay at hotels at very great expense, the length of time of enforced absolute rest is an important consideration. Accident-insurance companies are especially interested in the length of time during which they must pay weekly indemnities. It is very much for their interest to have the patients in these cases get well quickly. In saying that these patients will recover, when electrical massage is thoroughly used, in half the time required by other forms of treatment, a very conservative estimate is made.

Therapeutical Notes.

A Tampon for Cancer of the Uterus.—The *Riforma medica* for December 5th gives the following:

R Orthoform 15 grams;
Arsenious acid 1½ gram;
Alcohol, of each 120 minims
Water, A

M.

A tampon of absorbent cotton is saturated with this solution and applied *per vaginam*.

An Ointment for Infantile Impetigo of the Head and Face.—The *Riforma medica* for December 10th ascribes the following formula to Kistler:

R Salicylic acid 2 parts;
Bismuth subnitrate 10 "
Rose ointment 100 "
Powdered starch 15 "

M

Lanoform.—This is described (*Giornale di farmacia di Trieste*; *Gazzetta medica lombarda*, December 5th) as lanolin mixed with one per cent. of formaldehyde. It is used as an antiseptic.

The Treatment of Gastro-intestinal Intoxication in Infants.—Perrier (*Annales de médecine et de chirurgie infantiles*, November 15th; *Riforma medica*, November 23d) recommends in light forms unaccompanied by general phenomena, such as vomiting, diarrhœa, tumid abdomen, stationary or diminished weight, the suspension of milk, substituting for it boiled water, or slightly alkaline water, rice water, barley water, etc. The following prescription should be given:

R Benzonaphthol $\frac{1}{2}$ to 9 grains;
Salicylate of bismuth.... $\frac{7}{8}$ to 15 “
Syrup of orange flowers..... 450 minims;
Mucilage of acacia..... 1,350 “

M.

A teaspoonful every two hours.

If the dejecta are fetid, infrequent, and if there is tympanites, give:

R Calomel $\frac{3}{4}$ to $1\frac{1}{2}$ grain;
Sugar of milk..... 13 “

In those forms in which to the before-mentioned symptoms are added fever, fetid breath, foul tongue, thirst, and loss of weight, milk should always be suspended, water alone being given. Gastric and intestinal lavage with boiled water or a seven-tenths-per-cent. saline fluid should be practised; warm, moist compresses should be applied to the abdomen, and if there is hypothermia hot baths should be given, while tepid or cool baths should be used with hyperthermia. Thirty cubic centimetres (about four hundred and fifty minims) of artificial serum should also be injected every three or four hours.

Trigeminal Neuralgia.—Hirschkrone (*Gazzetta degli ospedali e delle cliniche*, December 23d) recommends the following:

R Extract of cannabis indica $\frac{7}{8}$ grains;
Salicylic acid 75 “

M. To make ten powders.

Three powders to be taken daily.

For Phthisical Diarrhœa.—De Renzi (*Riforma medica*, December 23d) recommends:

R Iodoform 30 grains;
Tannin 60 “

M.

Divide into ten powders. From two to four to be taken daily.

For Phthisical Constipation.—The same author in the same journal recommends:

R Iodoform 30 grains;
Naphthalin 30 to 60 “

M.

Divide into ten powders. From two to four to be taken daily.

A Plaster for Lupus of the Vulva.—The *Riforma medica* for December 9th gives this formula:

R Olive oil, {
Rosin, { each 8 parts;
Yellow wax, {
Gum ammoniac, { each 1 part;
Venice turpentine, {
Pyrogallie acid 4 parts.

THE

NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by
D. APPLETON AND COMPANY.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, FEBRUARY 4, 1899.

THE RANK OF THE ARMY MEDICAL OFFICERS.

If the course is followed which almost everybody expects will be pursued—that, namely, of our retaining the Philippine Islands—the country will require an army of more than a hundred thousand men, and that will call for a large increase of the medical corps. This has already been asked for by the surgeon-general. At a recent meeting of officers of the corps a special committee was appointed to gather the views of the department concerning those provisions of a bill before congress which relate to an increase of the medical corps. The committee, consisting of Colonel and Assistant Surgeon-General Dallas Bache, Lieutenant-Colonel and Deputy Surgeon-General Charles Smart, and Major and Surgeon Louis A. La Garde, has sent to the secretary of war, through the adjutant-general of the army, a statement of what seems desirable for promoting the efficiency of the medical corps. One of the capital points made is that a larger proportion of the medical officers should have high rank, so that any member of the corps may look forward to retirement, when he reaches the age limit of sixty-four years, with the rank next below that of the surgeon-general, that is to say, the rank of colonel. Under the present conditions, the committee remark, it not infrequently happens that a medical officer is retired with the rank of lieutenant-colonel, and sometimes with only that of major, and this after a lifetime of service requiring high professional attainments and involving heavy responsibilities.

The Hull bill provides for 500 medical officers in addition to the surgeon-general—10 (two per cent.) colonels, 20 (four per cent.) lieutenant-colonels, 110 (twenty-two per cent.) majors, and 360 (seventy-two per cent.) captains and lieutenants—while it provides for 569 other staff officers, of whom 48 (over eight per cent.) are to be colonels, 79 (nearly fourteen per cent.) lieutenant-colonels, 165 (twenty-nine per cent.) majors, and 277 (nearly forty-nine per cent.) captains and lieutenants. These provisions, the committee justly say, fail to do justice to the medical profession. Medical officers, they add, desire their responsibilities to be recognized, and that they themselves be endowed with as much rank, power, and position as offi-

cers of corresponding age and experience in the other staff corps. They therefore recommend that the Hull bill be amended so as to provide for 20 assistant surgeons-general with the rank of colonel and 30 deputy surgeons-general with the rank of lieutenant-colonel, and to reduce the number of assistant surgeons with the rank of captain and lieutenant from 360 to 340. The assistant to the surgeon-general, the chiefs of the large and active divisions in his office, the chief medical inspector and his assistants, the dean of the Army Medical School, the chief surgeons of home and colonial military departments, the officers commanding the general hospitals of from 500 to 1,000 beds, the chief surgeons of the large garrisons and camps assimilating a brigade organization, and the medical supply officers, they think, should all be colonels or lieutenant-colonels. They further recommend that promotions be made by seniority after the examination required by existing law has been passed.

The committee add that, were they to give full expression to their views of what is desirable and would be beneficial for the medical department and the army as a whole, they would urge the adoption of those parts of senate bill No. 4,900 which provide for 596 officers, comprising a surgeon-general with the rank of brigadier-general, 20 assistant surgeons-general with the rank of colonel, 30 deputy surgeons-general with the rank of lieutenant-colonel, 175 surgeons with the rank of major, 120 assistant surgeons with the rank of captain, and 250 assistant surgeons with the rank of lieutenant mounted. This would provide for a medical officer to every 168 men of an army of 100,000.

The statement concludes as follows: "We would, indeed, go further than the said senate bill when we consider the importance of the medical department of an army of 100,000. Whether it is viewed in the light of medical supply, involving the expenditure of large sums of money; in the light of sanitation, involving the military efficiency of the whole command; in the light of military administration over so many officers, hospital corps men, nurses, and hospital establishments; or in the light of caring for 10,000 men, or ten per cent. of the army—which is an average percentage of sick in times of active service—the importance of the work and the extent of the responsibilities appear to us to be more than equivalent to those of a division commander who has the rank of major general. The chief of the medical department in most European armies has the rank of major general. We, therefore, are of the opinion that in recognition of the great responsibilities attaching to the surgeon-general of such an army the officer holding this position should have the rank of major general, and that the

senior of the assistant surgeons-general should have the rank of brigadier-general."

For our part, we think the committee would have been abundantly justified in urging the elevation of rank mentioned in the last paragraph of their statement—that and nothing less. The growth of the army warrants it, and the importance of having the medical corps of the highest order demands it. Still, it is to be presumed that the gentlemen of the committee are wise in mentioning a list of minimum requirements, in view of what action congress might take or decline to take on propositions involving rather radical changes.

A HÆMORRHAGIC MICRO-ORGANISM.

C. KLEIN (*Centralblatt für Bakteriologie und Parasitenkunde*, xxii, 4; *Centralblatt für innere Medizin*, November 5, 1898), after alluding to the bestowal by the laity of a common name on various diseases of sheep, speaks of one of those diseases as being manifested by hæmorrhagic oedematous swelling of the groins and of the abdominal wall, proceeding from the vulva, in sheep that have recently dropped lambs, proving fatal in from twenty-four to ninety-eight hours. In the skinning of these animals three persons acquired a vesicular affection of the skin which seemed to have many points of similarity to the carbuncular manifestations of anthrax. The fluid contained in the vesicles had a bloody color. Besides the vesicles, there were observed in the human subject only erythema, swelling of the axillary glands, and local itching and irritation, but without any elevation of temperature. From the contents of the vesicles the author obtained by cultivation a staphylococcus-like micro-organism into the behavior of which on various media, together with its staining reactions, he goes largely, particularly as to the points that distinguish it from the micrococcus found by Nocard in cases of the gangrenous mastitis of sheep.

Clinically, the two organisms are chiefly distinguished from each other in their effects by the fact that Nocard's micrococcus gives rise only to transitory boils, while the micro-organism found by the author always occasions extensive hæmorrhagic oedema of the subcutaneous tissue and of the muscles. In several instances, also, hæmorrhagic enteritis and, especially after intraperitoneal injection, hæmorrhagic peritonitis have been observed. The small size of the liver is striking. The infection is almost always fatal. Inoculation is possible by the employment of preliminary inoculations with highly attenuated culture products, but the immunization is not perfect, for the subsequent inoculation of large quantities of the unattenuated product still

gives rise to the disease, although its development is postponed.

In two instances Klein has inoculated sheep with his micro-organism. One of the animals died, and the other recovered after having for a long time shown severe illness with a temperature of 106° F. From the sheep that died there was obtained a micro-organism that displayed the greatest virulence when inoculated into guinea-pigs.

MINOR PARAGRAPHS.

THE HOSPITAL PATIENT'S RIGHT TO SECRECY.

DR. EDMUND ANDREWS (*Journal of the American Medical Association*, January 7th) points out a much-neglected fact that the purposes of clinical instruction and hospital administration apart, and these are by implication waived by the patient on becoming an inmate of a hospital, the hospital patient has as much right to secrecy in regard to his affairs as the private patient. For instance, says Dr. Andrews, a patient in a hospital may have a claim, or perhaps a suit against a railway company for injuries received on its line. The hospital or its officers may not furnish to the railway company, or to any outside parties, any information about the injuries without the patient's consent. A patient may have syphilis, and the disease may be shown and fully explained to the clinical class, but it must not be divulged to his inquiring neighbors and friends, unless he desires it, which he probably does not. An agent of an accident insurance company often inquires about the condition of an injured patron, but it is not proper to inform him, unless the patient wishes it, and so of all other cases. The personal honor and the legal obligation of the surgeon are pledged to preserve the patient's secrets, except where necessarily waived for hospital purposes. The growing tendency to make sensational paragraphs for newspaper purposes out of the ailments of hospital patients renders this warning specially apposite; for it may be reasonably assumed that the information could not, in many instances at least, have been obtained without a grave dereliction of duty on the part of some of the hospital staff—doctors, nurses, students, or attendants—all of whom are in honor equally bound.

THE TREATMENT OF GRANULAR CONJUNCTIVITIS WITH SALICYLIC ACID.

THE *Presse médicale* for December 24th reports the treatment of granular conjunctivitis by M. Moby with local applications of salicylic acid. A solution of salicylic acid in alcohol of a strength of one in ten is used, and is applied to the granular surfaces with a pledget of absorbent cotton wound on a metallic holder and soaked in the solution and squeezed dry. A few seconds only are needed for the application. The treatment is said to be somewhat painful at first, but the pain quickly abates and then immediate relief is said to follow, much more marked in degree than with other topical applications. It lasts longer and becomes more marked with successive applications. The cornea, moreover, it is said, tolerates salicylic acid perfectly without giving rise to pigmentation should corneal ulcers be present. The cauterizations are repeated at first

daily, then every two days, and finally once or twice a week. No other treatment is called for in uncomplicated cases. This procedure certainly seems to merit a trial. The addition of one per cent. of cocaine to the solution would probably dispose of the only evident objection, the initial pain.

THE "SIGN OF THE SOU."

It seems that the *signe du sou* is the sound heard in a variety of auscultatory percussion in which a piece of metal is held against the point of the chest opposite the examiner's ear and struck with another piece of metal. Pitres published an article on its diagnostic significance in the *Nice médical*, 1898, No. 1, and Citron, whose abstract of Pitres's article appears in the *Deutsche Medizinische-Zeitung* for January 9th, proposes for the procedure the German name *Stäbchenplemmeterperkussion*. The sound transmitted by healthy lung tissue is described as dull and wooden. It is dull, too, when it comes through tuberculous or pneumonic foci, except when there is very extensive infiltration. When there is a large zone of air alone, as in pneumothorax, there is a "brazen" resonance. When there is a large area of perfectly homogeneous material, as in cases of extensive neoplasms, and especially in those of pleurisy with effusion, the sound is clear and silvery. If an area of dullness is found extending from above downward over one lung, one may sometimes be in doubt how far to attribute it to free fluid and how far to pneumonic infiltration. In such cases the *signe du sou* indicates the level of the layer of liquid, and in like manner the diagnosis may be made of pleuritic exudation and effusion.

SURGICAL OPERATIONS FOR THE DELECTATION OF REVELERS.

It was stated recently in the *Sun* that it had become the fad among the gay youngsters of Paris to amuse themselves after dinner with witnessing cinematographic representations of surgical operations, and that publicity had been given to the matter as the result of indignation on the part of a man who was present at such an exhibition when he recognized in the patient represented a well-known Paris lady. It is hardly to be supposed that such displays, if they show real operative procedures, can be arranged without the connivance of medical men, and we are loath to believe that men of our profession can be found to prostitute themselves to such base purposes.

POISONING BY HYSSOP.

At Birmingham, England, according to the *Lancet* for January 14th, a pregnant woman died from taking an infusion of hyssop. She was said to be a subject of Bright's disease. We are not told which variety of hyssop is referred to, and there are many varieties of this plant belonging to the natural order of *Labiata*, which order is commonly held to be harmless in its properties. We presume that the *Hyssopus officinalis* is the one in point.

THE ALKALINE TREATMENT OF STERILITY.

SOME additional evidence in favor of the treatment of functional sterility by alkaline vaginal injections is adduced in the *Revue médicale de l'Afrique du Nord*, cited by the *Revue médicale* for January 18th. M. Trou-

ette, a veterinary surgeon of Lyons, treated four hundred and thirty-six mares, which had been previously ineffectually covered, by means of vaginal douches containing seventy-five grains of bicarbonate of sodium in a litre of tepid water, administered an hour before copulation, the object, of course, being to counteract the hyperacidity of the vaginal mucus. No less than two hundred and seventy-seven of these mares became fecundated, a hundred and forty-eight remaining sterile, and fourteen being lost sight of. Old brood mares which had been pregnant for many years were thus fecundated, and one mare, eight years old, which had been covered unsuccessfully for three consecutive years, produced a fine foal.

A NEW REGIMENTAL BADGE FOR THE ROYAL ARMY MEDICAL CORPS.

THE efforts that have been recently made in England to place the army medical service on a footing in every way satisfactory to the profession of medicine should be appreciated by our transatlantic brethren. As trifles often indicate more than they express, we may be permitted to remark that the regimental device for the new corps, which we learn from the *British Medical Journal* for January 14th has been approved—viz., the serpent and rod intertwined, the insignia of the healing art almost from time immemorial, enbossed in a laurel wreath, surmounted by the imperial crown—seems to us particularly appropriate. The motto *In arduis fidelis* is also singularly felicitous.

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending January 28, 1899:

DISEASES.	Week ending Jan. 21.		Week ending Jan. 28.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	14	4	14	6
Scarlet fever.....	162	17	202	11
Cerebro-spinal meningitis.....	0	5	0	6
Measles.....	159	10	174	13
Diphtheria.....	180	26	197	30
Croup.....	12	9	10	3
Tuberculosis.....	189	176	200	191
Small pox.....	0	0	0	0
Chicken-pox.....	35	0	27	0

Conviction of a Christian Scientist.—We learn from the *Cleveland Journal of Medicine* for January that Harriet O. Evans, a "Christian Scientist" of Cincinnati, complacently allowed Thomas McDowell to die of typhoid fever without any treatment except the much-vaunted prayer of these peculiar people. Under the energetic initiative of Dr. Charles A. L. Reed, of Cincinnati, who is a member of the State board, she was prosecuted for practising medicine without a license. The police court jury is reported to have employed just twenty minutes in deciding that she was guilty as charged. The case has been appealed, of course, but it is a most excellent beginning. The thanks of the medical profession of the State, says the *Cleveland Journal*, are due to Dr. Reed for having shown in this and many other cases what a sincere and energetic member of the board can accomplish.

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, and cholera were reported to the supervising surgeon-general of the United States Marine-Hospital Service for the week ending January 28, 1899:

Small pox—United States.

Calvert, Ala.....	Dec. 10-Jan. 20.....	10 cases.	2 deaths.
Clarke County, Ala.....	Dec. 25-Jan. 1.....	Disease generally prevalent.	
Mobile, Ala.....	Jan. 20.....	5 cases.	
New Haven, Conn.....	Jan. 16.....	2 "	
Origin of the disease, New Durham, N. J.			
Washington, D. C.....	Jan. 21.....	1 case.	
Origin, Alexandria, Va.			
Pensacola, Fla.....	Jan. 15.....	1 case.	
Marion County, Kan.....	Jan. 18.....	11 cases.	
Origin, Oklahoma.			
St. Louis, Mo.....	Nov. 1-Jan. 21.....	15 cases.	2 deaths.
Nebraska City, Neb.....	Jan. 9-16.....	4 "	8 "
Dunkirk, N. Y.....	Jan. 7-14.....	3 "	
New York, N. Y.....	Jan. 7-14.....		1 death.
Altoona, Pa.....	Dec. 31-Jan. 23.....	1 case.	
Bedford, Pa.....	Dec. 31-Jan. 23.....	1 "	
Drumbaugh, Pa.....	Dec. 31-Jan. 23.....	2 cases.	
Charlesville, Pa.....	Dec. 31-Jan. 23.....	15 "	
Claysburg, Pa.....	Dec. 31-Jan. 23.....	1 case.	
Philadelphia, Pa.....	Dec. 31-Jan. 23.....	9 cases.	
Alexandria, Va.....	Jan. 20.....	1 case.	
Norfolk, Va.....	Jan. 16.....	90 cases.	

Small pox—Foreign.

Pretoria, Africa.....	Dec. 24.....	Small-pox epidemic suppressed.	
Antwerp, Belgium.....	Dec. 24-31.....	10 cases.	2 deaths.
Rio de Janeiro, Brazil.....	Dec. 3-16.....	21 "	9 "
Paris, France.....	Dec. 21-31.....		1 death.
Calcutta, India.....	Dec. 3-10.....		1 "
Chichualhua, Mexico.....	Jan. 7-11.....		1 "
Mexico, Mexico.....	Dec. 31-Jan. 8.....		4 deaths.
Moscow, Russia.....	Dec. 17-21.....	14 "	8 "
Odessa, Russia.....	Dec. 21-31.....		1 death.
St. Petersburg, Russia.....	Dec. 21-31.....	1 case.	1 "
Warsaw, Russia.....	Dec. 17-31.....		4 deaths.
Bagdad, Turkey.....	Oct. 22-Nov. 27.....	96 cases.	20 "
Officially reported.			
Constantinople, Turkey.....	Dec. 26-Jan. 2.....		11 deaths.

Yellow Fever.

Rio de Janeiro, Brazil.....	Dec. 3-16.....	10 cases.	10 deaths.
Barranquilla, Colombia.....	Dec. 17-21.....	1 case.	1 death.
Calcutta, India.....	Dec. 3-10.....		1 "
Vera Cruz, Mexico.....	Jan. 5-12.....		1 death.

Cholera.

Calcutta, India.....	Dec. 3-10.....		6 deaths.
----------------------	----------------	--	-----------

The Ninety-third Annual Meeting of the Medical Society of the State of New York opened in Albany on Tuesday, January 31st. The meeting was called to order at 9.15 A. M. by the president, Dr. John O. Roe, of Rochester. The Divine blessing was invoked by one of the local clergymen, after which the president read his inaugural address. He touched upon matters of interest to the profession, giving special attention to medical education, the adulteration of food, the abuse of medical charities, tuberculosis in cattle, etc. In speaking on the abuse of medical charities, he expressed the opinion that persons able to pay for medical advice should be prosecuted under the charge of obtaining money under false pretenses.

Following the president's address were the reports of the various committees. The reading of the report of the committee on legislation by a new member of the society raised a little breeze of discussion, as the adoption of recommendations of the report was objected to on that ground. The discussion, however, was only temporary. When the meeting was called to order the

were only eighty members present, but the number soon increased to the seating capacity of the hall, about one hundred and sixty.

At the time of our going to press it seemed probable that the nominating committee would recommend for the presidency an Albany physician who has ever been an earnest and efficient worker in the interests of the organization. It was confidently expected that he, with the united support of middle and western New York, would receive the nomination.

Under the twenty-minute rule the reading of papers progressed smoothly and rapidly, and, as they were not extensively discussed, the full programme for the day was finished at the close of the afternoon session. There was to be a brief evening session, and on Wednesday evening the annual banquet was to take place.

Among the notable papers presented was one by Dr. H. R. Hopkins, of Buffalo, on Hygienic Camps. In the discussion which followed its reading, the remarks made by Dr. William Warren Potter, also of Buffalo, were such as to deserve the heartiest commendation. He deprecated the tendency widely shown some time ago to criticise the conduct of the medical corps of the army.

Worthy of General Imitation.—According to the *Boston Medical and Surgical Journal* for January 26th, the following resolution has been adopted by the Rochester Pathological Society: If any member be confronted with a suit at law for alleged malpractice, or similar charge, it shall be his duty to notify the society. The president shall thereupon appoint a committee of three to investigate the merit of the action, to advise the member brought into litigation, and to recommend to the society such measures as they consider should be taken.

The St. Louis Medical Society.—At the last regular meeting, on Saturday evening, January 28th, Dr. Robert M. Funkhouser read a paper on Suppurative Puerperal Peritonitis with Nephritis; Coeliotomy; Recovery.

The Medical and Surgical Society of the District of Columbia.—At the ninety-first meeting, which was to be held in Washington, on Thursday evening, the 2d inst., the following papers were presented: The Causal Relations of Nasal Diseases to Diseases of the Eye, by Dr. Oscar McKimkie; and The Commitment and Detention of the Insane in the District of Columbia.

Changes of Address.—Dr. W. F. Donovan, to No. 337 West One Hundred and Forty-fifth Street; Dr. F. Mortimore, to No. 235 West One Hundred and Twenty-second Street; Dr. T. A. McNicholl, to No. 1919 Seventh Avenue; Dr. M. L. Tirrell, to No. 131 East One Hundred and Twenty-seventh Street; Dr. James P. Tuttle, to No. 42 West Fifthth Street.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Seven Days ending January 26, 1899:*

CARTLE, H. R., Surgeon. To report at bureau preparatory to detail for temporary duty in Cuba, January 23, 1899.

PETTEL, W. J., Passed Assistant Surgeon. To proceed to Port month, Va., for special temporary duty, January 26, 1899.

ROSENAT, M. J., Passed Assistant Surgeon. To proceed to Delaware Breakwater Quarantine for temporary duty, January 21, 1899.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 21 to January 28, 1899:*

BRADLEY, ALFRED E., Major and Brigade Surgeon, will proceed to Washington on business pertaining to the medical department of the army.

CARTER, W. FITZHUGH, Major and Surgeon, will proceed to Havana and report to the commanding general, Division of Cuba, for duty.

CULLEN, G. I., Captain and Assistant Surgeon, is honorably discharged from the service of the United States.

DAILY, WILLIAM F., First Lieutenant and Assistant Surgeon, is honorably discharged from the service of the United States.

EBERT, RUDOLPH G., Major and Surgeon, is detailed as a member of the examining board appointed to meet at Vancouver Barracks, Washington, vice WOLVERTON, WILLIAM D., Lieutenant-Colonel and Deputy Surgeon-General, retired from active service.

FISHER, HENRY C., Captain and Assistant Surgeon, will return to his proper station, Plattsburg Barracks, New York.

GANDY, CHARLES M., Major and Brigade Surgeon, will proceed to Fort Monroe, Virginia, for duty.

GARDNER, EDWIN F., Major and Surgeon, will proceed to Fort Logan, Colorado, for duty.

HALL, WILLIAM R., Major and Surgeon, will proceed to Washington and assume his duties as attending surgeon.

KERNACHAN, WILLIAM J., Major and Brigade Surgeon, will proceed to Anniston, Alabama, for duty.

O'BRIEN, A. P., Captain and Assistant Surgeon, is honorably discharged from the service of the United States.

RICHARD, CHARLES, Major and Surgeon, will proceed to Fort Monroe, Virginia, and assume command of the Josiah Simpson General Hospital at that post, relieving WOODHULL, ALFRED A., Lieutenant-Colonel and Deputy Surgeon-General. On being relieved, Lieutenant-Colonel Woodhull will proceed to Manila and report to the commanding general, Department of the Pacific, for duty as chief surgeon of that department, relieving LIPPINCOTT, HENRY, Lieutenant-Colonel and Deputy Surgeon-General. On being relieved, Lieutenant-Colonel Lippincott will proceed to Denver for duty as chief surgeon of the Department of the Colorado.

SHAKESPEARE, EDWARD O., Major and Brigade Surgeon, will proceed to Philadelphia to inspect apparatus for the sterilization of water.

SMART, CHARLES, Lieutenant-Colonel and Deputy Surgeon-General, is detailed as a member of the board of officers appointed to meet at the Army Building, New York, for the purpose of examining, testing, and reporting upon the various emergency rations as to their adaptability for use in the army.

TILTON, HENRY R., Lieutenant-Colonel and Deputy Surgeon-General, and HERVEY, PHILIP F., Major and Surgeon, are detailed as members of the army retiring board appointed to meet at St. Paul for the examination of such officers as may be ordered before it.

TIRRELL, HENRY S., Lieutenant-Colonel and Chief Surgeon, is honorably discharged from the service of the United States.

WOODRUFF, CHARLES A., Major and Brigade Surgeon, will report to the commanding general, Department of California, for duty in that department.

WYETH, MARLBOROUGH C., Captain and Assistant Surgeon, will report to the examining board appointed to meet at the Army Medical Museum, Washington, at such time after February 1st as he may be required by the board for reexamination for promotion.

Society Meetings for the Coming Week:

MONDAY, February 6th: New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society, New York (private); Brooklyn Anatomical and Surgical Society (private); Corning, N. Y., Academy of Medicine; Utica, N. Y., Medical Library Association; Boston Society of Medical Observation; St. Albans, Vermont, Medical Association; Providence, Rhode Island, Medical Association; Hartford, Connecticut, Medical Society; South Pittsburgh, Pennsylvania, Medical Society; Chicago Medical Society.

TUESDAY, February 7th: New York Neurological Society; Buffalo Academy of Medicine (Section in Surgery); Elmira, N. Y., Academy of Medicine; Ogdensburg, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Hudson, N. J., County Medical Society (Jersey City); Hampden, Massachusetts, District Medical Society (Springfield); Androscoggin, Maine, County Medical Association (Lewiston); Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore).

WEDNESDAY, February 8th: New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Society of the Alumni of the City (Charity) Hospital; Society for Medical Progress, New York; Medical Societies of the Counties of Albany and Allegany (quarterly), N. Y.; Pittsfield, Massachusetts, Medical Association (private); Philadelphia County Medical Society.

THURSDAY, February 9th: Society of Medical Jurisprudence and State Medicine, New York; Brooklyn Pathological Society; New York Laryngological Society; Medical Society of the County of Cayuga, N. Y.; Jenkins Medical Association, Yonkers, N. Y.; South Boston, Massachusetts, Medical Club (private); Pathological Society of Philadelphia.

FRIDAY, February 10th: Yorkville Medical Association, New York; Brooklyn Dermatological and Genito-urinary Society (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties, N. Y.

SATURDAY, February 11th: Obstetrical Society of Boston (private).

Births, Marriages, and Deaths.

Married.

ANDERSON—REGNA.—In New York, on Thursday, January 26th, Dr. John Cameron Anderson and Mrs. Henry Milton Regna.

ROBINSON—COATES.—In Goshen, N. Y., on Wednesday, January 25th, Mr. Arthur R. Coates and Miss Mary Verplanck Robinson, daughter of Dr. Herman H. Robinson.

DENISON—STIVERS.—In New York, on Tuesday, January 24th, Dr. Charles Ellery Denison and Miss Mary Frances Stivers.

FISCHER—HILDBRETH.—In New York, on Wednesday, January 25th, Dr. Charles Sumner Fischer and Miss Florence Adelaide Hildbreth.

LOWDEN—MURRAY.—In Flushing, Long Island, on Saturday, January 21st, Mr. Thomas W. Lowden and Dr. May M. Murray.

HANLON—MEEKER.—In Lecompte, Louisiana, on Wednesday, January 25th, Mr. James D. Hanlon and Miss Matilda Meeker, daughter of Dr. Samuel F. Meeker.

SMITH—SHEA.—In Brooklyn, on Tuesday, January 24th, Dr. Isaac Beckett Smith and Miss Loretta Shea.

SUTPHEN—BLANCHARD.—In North Conway, New Hampshire, on Tuesday, September 21, 1897, Dr. Carlyle E. Sutphen and Miss Edna Ethel Blanchard.

WEIST—CILLEY.—In New York, on Wednesday, January 25th, Dr. Henry H. Weist, of Richmond, Indiana, and Miss Alice Longfellow Cilley.

YANDELL—WILSON.—In Canton, Mississippi, on Saturday, January 21st, Dr. William M. Yandell and Miss Nellie Moore Wilson.

Died.

CULVER.—In Albany, on Monday, January 23d, Cyrus Lee Culver, son of Dr. Charles M. Culver.

LOCKWOOD.—In Charleston, South Carolina, on Saturday, January 21st, Dr. Joseph D. Lockwood, in the forty-third year of his age.

LYTLE.—In Princeton, N. J., on Sunday, January 22d, Dr. William J. Lytle, aged seventy-five years.

McMILLAN.—In Biloxi, Mississippi, on Friday, January 27th, Dr. W. P. McMillan, aged sixty-eight years.

SKINNER.—In Detroit, on Tuesday, January 24th, Dr. Eugene Carroll Skinner, in the fifty-ninth year of his age.

SMITH.—In New York, on Saturday, January 28th, Dr. Judson C. Smith, in the thirty-third year of his age.

TAYLOR.—In Los Angeles, California, on Wednesday, January 25th, Dr. Charles Fayette Taylor, in the seventy-third year of his age.

Obituaries.

CHARLES FAYETTE TAYLOR, M.D.

DR. TAYLOR, who died in Los Angeles on January 25th, retired from a practice more than a decade ago. Up to that time he was active and progressive in the cultivation of orthopaedic surgery in New York. It was to his efforts that was due the establishment of the New York Orthopaedic Dispensary and Hospital. He contributed largely to the literature of orthopaedics and of the therapeutical employment of electricity, and invented a number of original and valuable mechanical appliances for the correction of deformities.

Dr. Taylor was born in Vermont. He was in his seventy-second year at the time of his death, which is said to have been occasioned by pneumonia. He was a

graduate of the medical department of the University of Vermont, of the class of 1856. He was as much esteemed for his manly and genial qualities as for his professional attainments. In accordance with his earnest wish, his remains were cremated.

THE LAW IN ITS RELATIONS TO PHYSICIANS.

By ARTHUR N. TAYLOR, LL. B.

IV.

THE RIGHT TO PRACTISE MEDICINE AND SURGERY.

(Continued from page 133.)

A Medical College can not Arbitrarily Refuse Examination.—While the following illustration is not strictly pertinent to the subject in consideration, it shows how the courts apply the policy above illustrated to protect students from the arbitrary action of medical colleges as well as applicants from the unjust discrimination of examining boards. A medical student who had paid his fees and fulfilled all of the other conditions entitling him to present himself for final examination, was informed by the secretary of the faculty that he would not be allowed to present himself for final examination, nor would he be granted a degree of doctor of medicine. Upon a writ of mandamus the matter was brought before the court and an order issued requiring the examination of the student. The opinion of the court is both interesting and instructive, and is therefore quoted from at length. "In answer to this application the respondent (the medical college) presents no ground whatever for its action, but insists that it has the right arbitrarily, without any cause, to refuse the relator (the student) his examination and degree. It seems to us clear that such a position can not for a moment be entertained. The circulars of the respondent indicate the terms upon which students will be received, and the rights which they were to acquire by reason of their compliance with the rules and regulations of the college in respect to qualifications, conduct, etc. When a student matriculates under such circumstances, it is a contract between the college and himself that, if he complies with the terms therein prescribed, he shall have the degree, which is the end to be obtained. This corporation can not take the money of the student, allow him to remain and waste his time (because it would be a waste of time if he can not get a degree) and then arbitrarily refuse, when he has completed his term of study, to confer upon him that which they have promised—namely, the degree of doctor of medicine, which authorizes him to practise that so-called science. It may be true that this court will not review the discretion of the corporation in the refusal for any reason or cause to permit a student to be examined and receive a degree; but where there is an absolute and arbitrary refusal there is no exercise of discretion. It is nothing but a willful violation of the duties which they have assumed. Such a proposition could never receive the sanction of a court in which even the semblance of justice was attempted to be administered." *

Qualification of Previous Practice.—The particular period of practice of medicine which shall be accepted by the examining board or other body having authority to grant licenses, as tantamount to a proper diploma or satisfactory examination, is fixed and described by the statute of each State recognizing such mode of qualification, and in order to determine whether in any given State a candidate is qualified by his former practice to receive a license to continue in his practice recourse must be had to the statute of that State. If by a fair interpretation of the meaning of the statute the candidate has fulfilled the requirements, nothing remains but to grant the license or certificate; if, on the other hand, it does not appear that the candidate has fulfilled the requirements of the statute, such license or certificate should be refused. A recent case of some interest arose in Rhode Island, where the law provides that a physician should have "reputably and honorably" engaged in the practice of medicine prior to January 1, 1892. The applicant, who was in the shoe business, took up the study of medicine by himself during the year 1889. In the latter part of that year he began to practise, after which time he gave his whole attention to the practice of medicine, leaving his shoe business to the management of clerks, and continued his practice up to January 1, 1892, some of his patients being satisfied with his services and some not. The court said: "There is no evidence that on January 1, 1892, he had come to be regarded by the community in which he practised as a skillful and successful practitioner, and therefore had acquired the honorable reputation as a physician necessary to qualify him to practise contemplated by statute. The decision of the health board in denying a certificate is confirmed." *

In Ohio the question arose some years after the passage of an act providing that ten years of continuous practice of medicine should qualify a physician for a continued practice, whether time spent in the practice of medicine since the act should be included as part of the ten years. The majority of the court were of the opinion it should be, and it was accordingly so held. †

Registration of Certificate.—It will be remembered that the law generally provides that the physician must register his certificate or license with some designated county officer in the county in which he resides, or, if he is a non-resident, in the county in which he intends to practise; but with the exception of one or two States the statute is silent as to the right of a physician to attend patients in counties other than the one in which his certificate is recorded. Whether or not this right does exist, and if so to what extent, is a very important question, but as the matter is regulated by statutes which differ in the several States no general rule can be laid down for all States; an examination, however, of decisions which have been rendered on the subject in several States will, it is hoped, lead to a clear understanding of the governing principle.

A case was decided in the supreme court in New York in 1890 upon the following facts: A physician, duly licensed by the State board and registered in Kings County, made numerous visits to a patient living in Westchester County. The court said: "No new registry is needed to visit a patient out of the county. The fact that a physician gives two days in a week out of his county to see patients does not make a new practice in

* *People, Cecil vs. Bellevue Hospital Medical College*, 38 N. Y. S. R., 418; 11 N. Y. Supp., 199.

* *Paquin vs. State Board of Health*, 33 Ad. R., 870.

† *Witt vs. Cutler*, 37 Ohio St., 317.

a new county, unless intended as a cover for a real change of place. It is simply practising medicine in Kings County with patients in another county." * The court intimated that the opening of an office or establishing a place of meeting patients in another county would not be a violation of the law, but no court in the State seems to have expressly committed itself to this extent.

In Texas the law requires the physician to register his certificate with the clerk of the district court in the county in which he may "reside or sojourn." Under this statute the practitioner must, upon changing his residence to another county, register his certificate again with the proper officer in the county to which he has removed.†

And so in Pennsylvania, under a similar statute, a practitioner who is properly registered in one county and opens and maintains an office in another county must register his certificate in such other county as a "sojourner."‡

It is fair to conclude from the cases considered that in all States having statutes similar to New York, providing that a license or certificate shall be granted by a State board which shall be good in any part of the State, and which must be filed with the proper county officer in the county in which the practitioner resides, the practitioner may safely have and attend patients outside of the county in which his certificate or license is filed; but it can not be safely advised that he would have the right to open an office outside of his county, or have a regular place of meeting patients without the county, or even associate himself in partnership with a physician where the partnership office was located without the county, until he had filed or registered his certificate or license in such other county.

In Indiana the license to practise is not granted by a State board and recorded in the particular county in which the physician intends to practise, but the license itself is granted by the clerk of the district court of the county in which the physician intends to practise. The law of that State is therefore construed much more strictly, necessitating that a license be taken out in every county into which the physician's practice extends.

Chief-Justice Elliott, of the supreme court of Indiana, in an opinion in which he held the law to be as above stated, expressed his opinion regarding a qualification of this construction in the following words: "It may be that there are cases where the law would hold that the statute does not apply in its full rigor, as where there is an emergency demanding prompt action, or where there is a professional visit for consultation, or the call is made because of some special skill or ability of the physician in a particular branch of his profession." §

Eight years later, in 1894, a case was decided by the appellate court of Indiana approving of Justice Elliott's remarks so far as they relate to emergency cases, but refusing to hold that the law would permit a physician to enter the county and practise "because of some special skill or ability of the physician in a particular branch of his profession." In this case the physician was called from an adjoining county to perform an amputation immediately necessary to save the patient's life,

he being the nearest physician with the requisite skill. After performing the operation he attended the patient and dressed the wound several times. The court held that, the county seat being sixteen miles away, to which place it would have been necessary to go for a license, it would have been impracticable to have obtained the license before performing the operation, and therefore the physician was legally justified in amputating the leg, but that his subsequent visits were unlawful.*

In regard to States like Indiana in which the license to practise is issued by a county officer entitling the physician to practise in that county instead of by a State officer or board, it will be necessary to procure a license in each county into which the physician's practice extends.

Excusable Failure to Register Certificate.—There are certain circumstances under which the physician is legally excusable for failing to properly file his certificate before practising. Such circumstances may result through ignorance of law or inadvertence on the part of the physician, as, where he honestly endeavored to comply with the law, but through error filed the certificate with the wrong officer.†

Or through ignorance of fact, as, where the physician delivered his certificate with the proper fee for recording the same to a third party, who promised to record it at once, but through sickness or other cause failed to keep his promise.‡

Or such circumstances may result from the neglect or carelessness of the officer whose duty it is to register the certificate, as, where the physician applied to the proper officer to be registered, but was informed by the officer that he could not register him for he had no book in which to enter the record.§

Under any of these circumstances the physician must have acted in good faith in his original endeavor to comply with the law, and if he desires the protection of the law to continue he must, as soon as he learns of the failure of his effort to comply, use all due means to secure the prompt filing or recording of his certificate.

Itinerant and Traveling Doctors. Who are.—The statutes of several States contain restrictions imposing burdens upon itinerant or traveling doctors, these statutes differing considerably in their form and manner of expression. No general rule can be given for determining who come within their scope. A statute in Texas is as follows: "From every physician, surgeon, oculist, or medical or other specialist of any kind, traveling from place to place in the practice of his profession, an annual tax of fifty dollars in each county where he may practise his profession" shall be collected. A medical specialist having two offices, one at his home and one in an adjoining county, where he met patients twice each month, is not within the meaning of this law. The court said: "Here the physician or specialist had two places of business; part of his time he spent at one and the other part of his time at the other place. This does not carry with it the idea of itinerancy, or traveling from place to place, as we understand the meaning of this term, within the provisions of the law." ||

§ Parish v. Cook, 75 Cal., 439.

|| Hamilton v. State, 26 Tex. Civ. Rep., 17, 18 S. W. Rep., 838.

* Martner v. Kirk, 55 Hun., 171.

† Holland v. State, 7 Tex. App., 69.

‡ Ege v. Commonwealth, 9 Ad. R., 471.

§ Orr v. Meeks, 111 Ind., 40.

Rhode Island, among other restrictions upon the medical profession, provides that nothing shall "authorize any itinerant doctor to register or to practise medicine in any part of the State." A physician who resided in Boston, and made a specialty of the treatment of catarrh, made regular visits to Providence in the practice of his specialty. The evidence showed that he had also been accustomed to visiting Worcester, New Bedford, Springfield, and Lowell, Massachusetts. The State board of health decided that he was to be regarded as an itinerant doctor, within the meaning of the statute. Upon review of the decision by the supreme court the conclusion of the board was approved of and affirmed.*

These two cases show facts not very greatly differing, yet it is evidently between the two that the line of demarcation must be drawn.

What Constitutes Practising Medicine.—It has been observed that the law does not exclusively recognize any particular system of medicine or class of practitioners, the legal signification of the term doctor being simply a practitioner of physic. The statutes of several States have defined what shall constitute practising medicine, with a tendency to extend rather than restrict the judicial definition of the term.

It has been held that one exercising the functions of a clairvoyant in the treatment of disease is rendering "medical services."† Also one practising Christian Science comes within the meaning of the statute making it unlawful for one not duly qualified to "operate on, profess to heal, or prescribe for or otherwise treat any mental or physical ailment of another."‡ Midwifery has been held to form an important department of surgery, and to come within the meaning of an act prohibiting the practice, by persons not qualified, of medicine and surgery in any of its branches.* And so one giving electric treatment comes within the law regulating the "practice of medicine and surgery."|| And also one who professes and practises bonesetting and reducing sprains, swellings, and contractions of the sinews, by friction and fomentation, comes within the operation of the statute regulating the "practice of physic and surgery."‡

While the definitions given seem plain and explicit, it is often a very nice question whether one, not having the legal qualification to practise medicine and surgery, has performed acts which will render him amenable to the law. Whether or not a particular case comes within the law is usually a question of fact for the jury to determine. Upon what evidence a jury will find that one has or has not practised medicine it is impossible to say with any degree of certainty, there being so many things, aside from the testimony given, that the jury may take into consideration. The best manner of illustrating this is by examining the facts upon which juries have passed and considering their verdicts.

Illustrations.—In the case of *Richardson vs. State*, decided in Arkansas in 1886, the State introduced the following evidence to show that the defendant practised medicine:

Mrs. Alice Stewart said: "I am acquainted with J. K. Richardson. I was acquainted with Mrs. Hattie Goff. I was present on two occasions when J. K. Rich-

ardson was at Mrs. Goff's when Mrs. Goff requested me to get some money of hers and give it to J. K. Richardson. Mrs. Goff was afflicted with dropsy and cancer. Dr. Brandon treated her for dropsy. I saw J. K. Richardson there with Dr. Brandon at Mrs. Goff's several times, with H. Brandon. J. K. Richardson came several times by himself and applied medicine and plasters to Mrs. Goff's cancer. I understood that J. K. Richardson had charge of the money that I handed him at the request of Mrs. Goff." Upon cross-examination witness said: "I might have sworn on the trial before of this cause, that I did not know anything about a contract with J. K. Richardson and Mrs. Goff."

The defendant offered in his behalf a deposition by H. Brandon, who said: "That during the fall and summer of last year (1885) I was practising medicine in the city of Eureka Springs, Arkansas. That while there, perhaps in the latter part of September or October, 1885, I met Dr. J. K. Richardson, who was not eligible to the practice of medicine. At the time he spoke to me he claimed to be a student of medicine, and said he wished to continue his studies under me; that if I would furnish him the books, and give him all the instructions I could, he would compensate me as much as he could; said he had but little money, but was in possession of a very excellent remedy for curing cancer. I told him if he would give me his treatment for cancer that I would get the books and take him as a student and give him instructions as much as possible, to which we agreed. He then went into my office as a student of medicine. While he was with me I treated several cases of cancer, among whom was a Mrs. Goff. I agreed to doctor her for five dollars a week, which she paid. At different times I told Dr. Richardson to go and see the case and report to me the condition of the same. I told him on several occasions that if any one wanted to pay him any money he might receive it and report the same to me, which he did on one or two occasions. Mrs. Goff paid him some money, which he turned over to me. Dr. Richardson never collected any money that he did not turn over to me while he was in my office to my knowledge."

In this case the jury apparently disregarded the deposition of Dr. Brandon and, looking alone to the evidence given on behalf of the State, found that the defendant treated Mrs. Goff for a certain disease and received money for the same.*

In the case of *Nelson vs. State*, decided in Alabama in 1893, the evidence showed that the defendant, being called to attend a child who was sick, responded to the call and administered medicines; that he called once or twice, but did not make any charge and did not receive any pay; that he was called doctor by his neighbors. Defendant in his own behalf testified that he called upon the child and administered certain herbs that he found in the woods; that he did not claim to be a physician or represent himself to be one, and that he made no charge for his visits, and received nothing therefor. The jury found the defendant guilty of practising medicine; but the supreme court, in reviewing the case on appeal, reversed the judgment and sent the case back to the circuit court for a new trial.

Justice Coleman, in delivering the opinion, said: "It was the duty of the court to instruct the jury, as a matter of law, what acts amounted to a violation of the statute, and it was for the jury to ascertain whether the facts existed. We are of the opinion that it is not a violation

* *Evans vs. State Board of Health*, 33 Atl. R., 878 (R. I.).

¶ *Hewitt vs. Charier*, 16 Pick., 353.

* *Richardson vs. State*, 47 Ark., 562.

of the statute for a person who does not solicit patronage, who does not hold himself out as a physician, and does not pretend to be a physician, but simply advises or gives medicine to sick persons, merely as a neighbor or friend, and makes no charge, and does not expect any compensation for his services.*

In the case of *State vs. Hale*, tried in Missouri in 1852, the evidence did not show that the defendant received any compensation for the services in question. The court refused to instruct the jury "that unless they believed from the evidence that the defendant received compensation for his services as a physician, that they must find him not guilty," but instructed "that unless the jury believes from the evidence that the defendant practised medicine for compensation and reward, then he is not guilty, but the State is not required to prove the actual receipt of such compensation," upon which instruction the jury found the defendant guilty. The statute upon which this prosecution was based was as follows: "No person or copartnership of persons shall follow the practice of law or medicine, in whole or in part, as a business in this State without first obtaining a license to follow such profession according to the provisions of this act." The supreme court, in reviewing the case on appeal, held that the instruction given to the jury by the trial court correctly stated the law applicable to the case.†

It will be observed from these illustrations that in all three cases the juries found the defendants guilty. In the *Richardson* case the supreme court, upon appeal, criticised the verdict, and intimated that it was an injustice, but, finding no error of law in the trial, it declined to interfere with the verdict. In the *Nelson* case the supreme court found that the trial judge had erred in giving or refusing to give certain instructions to the jury, and therefore sent the case back for a new trial with statements of law relative to the evidence adduced, which probably resulted in a different verdict on the new trial. While in the *Hale* case the supreme court expressed its approval of the instruction given, and affirmed the judgment without any comments upon the verdict.

A case apparently in conflict with the *Hale* case comes from Rhode Island; the *Rhode Island* case is, however, based upon a statute providing that the unqualified practitioner shall not practise medicine or surgery "for reward or compensation." Under such a statute the instruction that "if the jury find that the defendant received no reward or compensation for his services, they must find for the defendant," is proper, and the court would commit an error if he refused to give such an instruction.‡

In view, however, of the statute existing in Rhode Island there is nothing in this case really in conflict with the law as expressed in *State vs. Hale*.

In the case of *Benham vs. State*, arising in Indiana, the evidence showed that the defendant issued circulars signed Dr. —, in which he claimed that his "treatment" of his "patients" would effect a "complete cure" of the opium habit. He also issued a number of letters from former patients addressed to him as "Doctor," testifying to the efficacy and success of his "treatment" of the opium habit. The heading of the letters and receipts given by him to his patients was: "Office of Dr.

—, No. — Street. —, Indiana." The counsel for defendant contended that the opium habit was not a disease; the jury, however, rendered a verdict of guilty, and the supreme court, upon reviewing the case, was of the opinion that the verdict was fairly sustained by the evidence.*

In a Michigan case, a party who exhibited upon a sign "Dr. —, Magnetic Healer," and who was called to visit and treat sick persons, and who made a certificate of death and a report of infectious diseases, was found to be holding himself forth as a medical practitioner.†

The selling of patent or proprietary medicines by one who does not pretend to diagnose a disease is in no way a violation of an act prohibiting the practice of medicine and surgery; yet if one examines patients, diagnoses their diseases, and then prescribes or sells his own proprietary remedies, he is practising medicine, notwithstanding the ostensible and apparent motive of the defendant may be the sale of his medicines.‡

And a man who travels from place to place with a band of music or other means of collecting people together for the purpose of selling them medicines, and in his speeches, advertisements, and pamphlets sets forth the symptoms of disease and prescribes ten different remedies as capable of curing all of such diseases, is practising medicine.§

In 1831 the supreme court of Ohio held that prescribing and administering medicine to two people for a fee sufficiently shows the party to have acted in the capacity of a physician.¶ And in 1879 the court of appeals of Texas held that the proof of attending and prescribing for a single case by one not legally qualified to practise medicine was sufficient to support a conviction for unlawfully practising medicine.‡

In accordance with the spirit manifested in the above decision, the supreme court of Nova Scotia held that one who applied plasters to tumors and cancers and gave directions for poulticing them was practising medicine.‡

It will be clearly seen from the preceding illustrations that it is the policy of the law to protect the people from the ignorance and unskillfulness of the pretender or quack in all branches of medicine. The law does not, however, go to the extent of including within its restrictions one who professes to cure by manipulation of the hands, by rubbing, kneading, and pressure, such treatment being considered by the courts to be harmless, if not beneficial, and to not come within the scope of the practice of either medicine or surgery.‡

In the trial of a case in the United States circuit court, of the sort above considered, the question arose whether or not the patient, who was called as a witness, could be compelled to produce the medicine he had received from the defendant charged with practising medicine unlawfully. The court held that he could not. Had, however, the case been one of a different sort, it is altogether probable that he would have been required to produce the medicine.‡

Emergency Cases.—The statutes of many States except from their operation services rendered in case of emergency. The question of what is an emergency was considered by the supreme court of California, in 1886, in the case of *People vs. Lee Wah*.

In this case two women who had been unable to obtain relief from their physicians called upon defendant and stated their ailments. He prepared herbs of his own selection and delivered them to the women, who took them as directed. The instructions given by the trial judge to the jury, which were approved by the supreme court, state the law fully as to what is an emergency. The following is an extract from these instructions: "Two ladies have testified before you and stated that their condition was deplorable; that they consulted in vain other physicians; and that they regarded themselves, and were regarded by their friends and physicians, as incurable, and that they repaired to this defendant as a last resort. The ladies stated upon their part it was an emergency—an exigency in which death on the one hand, and submitting themselves to that treatment on the other, were the only alternatives. I instruct you that the emergency contemplated by the statute is not such as this case suggests. It means a case in which the ordinary medical practitioners of the schools provided for by the statutes, who are provided with the proper diplomas, and have submitted themselves to the proper examination, are not readily obtainable. This is an emergency—as where the exigency is of so pressing a character that some kind of action must be taken before such parties can be found. . . . If, however, a party is satisfied that another school of physicians or another individual can render him more efficient aid—more beneficial services than others—and he therefore seeks his aid, that is not such an emergency as the statute contemplates."*

License from Irregularly appointed Board.—A physician can not be prosecuted for practising medicine and surgery unlawfully because his license is granted by a board of medical examiners which is improperly constituted, the appointment of the members being irregular, or even unconstitutional. Such a body would be a *de facto* board, and the certificates or licenses issued by it would be sufficient to protect the parties to whom they were issued from prosecution under the statute.†

Improper Refusal of Certificate no Defense.—In a prosecution for practising medicine and surgery without a certificate the defendant can not show as a defense that the board of examiners acted improperly or unlawfully in refusing to grant him a certificate.‡

(To be continued.)

Book Notices.

A System of Practical Medicine. By American Authors. Edited by ALFRED LEE LOOMIS, M. D., LL. D., Late Professor of Pathology and Practical Medicine in the New York University, and WILLIAM GILMAN THOMPSON, M. D., Professor of Medicine in the Cor-

nell University Medical College, etc. Volume IV. Diseases of the Nervous System and Mind—Vasomotor and Trophic Disorders—Diseases of the Muscles—Osteomalacia—Rhachitis—Rheumatism—Arthritis—Gout—Lithæmia—Obesity—Scurvy—Addison's Disease. Illustrated. Lea Brothers & Co., 1898. Pp. 5 to 1120.

THE fourth and concluding volume of this excellent *System* is devoted largely to a consideration of the disorders of the mind and nervous system, and the articles throughout the volume are of that high order of excellence which has characterized the work from its inception.

The peripheral nerves and their diseases are first considered, and then there are chapters upon the spinal cord. Noteworthy among them is one upon the diagnosis and localization of spinal-cord diseases. Indeed, this chapter and that upon cerebral localization are among the most striking of the volume. Another chapter which should be cited in particular is the very complete and excellent presentation of neurasthenia. It is not easy, however, to cite instances of unusual merit in this volume, for throughout there is an evenness about it which, being an evenness of a superior order, is delightful. Exhaustiveness, too, is an attribute of this volume; nervous and mental diseases have seldom received a more ample exposition. The volume is concluded with a number of the usually "unclassified" diseases, which naturally include osteomalacia, rickets, rheumatism, gonorrhœal arthritis, arthritis deformans, gout, lithæmia, obesity, scurvy, and Addison's disease. The illustrations are noteworthy, especially those diagrams which concern brain and cord localization.

In conclusion, we are glad to express our satisfaction and approval in connection with this system. It can scarcely fail, we think, to receive a warm and general approval.

A System of Medicine. By Many Writers. Edited by THOMAS CLIFFORD ALBUTT, M. A., M. D., F. R. C. P., F. R. S., F. L. S., F. S. A., Regius Professor of Physic in the University of Cambridge, etc. Volume VI. New York and London: The Macmillan Company, 1898. Pp. xii-1058. [Price, \$5.]

IN the sixth volume of Allbutt's *System* the study of respiratory disorders is completed and the consideration of circulatory diseases is entered upon. Bronchitis in its varying forms is first presented, and most ably. Disorders so well known as the bronchitides are scarcely susceptible of very unconventional handling, and good arrangement and completeness are the qualities most required. In the present instance both are noticeable. A chapter upon bronchiectasis, which follows, is the best presentation of the subject that we have seen and highly exhaustive. The pneumonias follow, and then pulmonary phthisis. The considerations of these subjects are quite what (by this time) everybody would expect of anything contained in this system. Indeed, the work of the reviewer in the case of this production is rather difficult, for, having once called attention to the exhaustiveness and ability, and above all the evenness, of the work, he can do nothing save to pick flaws—if, indeed, they can be found. Pneumoconiosis, pulmonary aspergillosis (a rare condition well described), pulmonary emphysema, asthma, and hay fever, syphilitic disease of the lungs, and the consideration of the pulmonary dis-

* *People vs. Lee Wah*, 71 Cal., 80; 11 Pac. Rep., 841.

† *Brown vs. People*, 11 Colo., 169; 17 Pac. Rep., 104; *Harding vs. People*, 16 Colo., 387; 15 Pac. Rep., 727.

‡ *Kroenstat vs. State*, 15 Ohio Cir. C. R., 73.

The plenritic diseases form the subject of the succeeding section.

The sections upon the circulatory diseases are begun with generalizations upon the blood and a discussion of its clinical examination, which are direct and simple—as they should be—and therefore useful and somewhat unusual. A chapter follows upon cardiac physics, and here again we have an example of that excellent feature of this *System*, the use of physiological introductions and generalizations as preparatory to the study of the various organs when diseased. Could anything be better calculated to aid the student?

Chlorosis is the first disorder we meet with among the circulatory diseases, and then come pernicious anæmia, splenic anæmia, hæmophilia, hæmorrhages in newborn children, purpura, scurvy, hæmoglobinuria, leucocythæmia, and dropsy. The arrangement of these disorders is somewhat peculiar and rather awkward, but the subject matter is the reflection of the most modern thought and research.

The diseases of the heart itself are next taken up. They include congenital malformations, the diseases of the pericardium (a chapter beyond praise), functional disorders of the heart, mechanical strain of the heart, and injuries by electric currents of high pressure. Simple and infective endocarditis come next, and, with the diseases of the myocardium, constitute the basis for the regional study of cardiac disease. The chapters which conclude this volume are devoted to this study and concern the aortic area of the heart and the mitral valve respectively.

La Chirurgie intramédiastinale postérieure. Avec figures dans le texte. Par Dr. J. POTARCA (de Bucharest). Paris: Carré et C. Naud, 1898. Pp. 110.

THE author of this interesting surgical monograph has made important anatomical studies of the relations of the pleural cavities to the structures contained in the posterior mediastinum and their operative accessibility. In connection with these studies, and to illustrate them, a considerable number of the recorded cases of operative procedures on the esophagus and bronchi by the posterior route has been collected from literature and are thus rendered easily accessible to the reader. The subjects treated of are chiefly the removal of foreign bodies from the esophagus and bronchi and the treatment of strictures and new growths of the esophagus. Mediastinal abscesses and tumors are also considered as within the realm of surgical interference.

William Stokes, His Life and Work (1891-1898).
By his Son, WILLIAM STOKES, Surgeon in Ordinary
to the Queen in Ireland. New York: Leonard
Green, & Co., 1898. Pp. 9 to 256.

There is a story told which any one might read to his benefit and which the youthful medical man would do well to be guided by. The life of Stokes was full of lofty ambition and of purpose, and, since able to do so, was his, the achievement of success could not but follow. Although his medical life was well rounded and complete and he was both teacher and practitioner, it was in the former capacity that he was preeminent, not only because of his masterly writings upon thoracic diseases

but even more because of the methods of clinical teaching which he introduced. Already the teachings of Laennec had revolutionized the diagnostic art, but the subject had by no means been exhausted, and there was a field in which the peculiar talents of Stokes were well fitted to busy themselves and whence there came his elaboration of physical diagnosis.

The lives of great men are necessarily interesting in a measure, for success is ordinarily attractive to contemplate for itself, but interest and admiration in these cases are often wide apart. It is not so in the case of Stokes, for, while our interest indeed is aroused by the story of his life, our regard, too, is equally great. There was something so manly and so noble in his nature, and at the same time so gentle, that we can not wonder at his having been beloved, since even to read the story of his life is to conceive an affection for him. A beautiful story, however, may be spoiled in the telling, but such is not the case here, for the simplicity and beauty of the narrative are thoroughly in harmony with its subject and unite with it to produce the pleasure a reading of the book affords. It is one that medical men would do well to read.

Sir Benjamin Collins Brodie. By TIMOTHY HOLMES, M. A., F. R. C. S. New York: Longmans, Green, & Co., 1898. Pp. 9 to 256.

THE life of Sir Benjamin Brodie has well been made the subject of a volume in the *Masters of Medicine* series, for, while his was no career of startling discovery or in any sense epoch-making, it was one of earnest purpose crowned with success, and one, moreover, of a time sufficiently recent to permit of a sympathetic reading.

Brodie's character was firm to the point of sternness, and determination marked his career throughout. It is true he did not have to contend against the obstacles that in so many lives have retarded or prevented success, yet all that came to him was from his own endeavor. The life that was Brodie's is capable of duplication in our time, and in fact we see from time to time professional careers which remind us of his, lives of men who have risen to contemporary eminence and success as practitioners and teachers, rather than lives in any more brilliant and lasting sense remarkable. A master of medicine in the former class Brodie unquestionably was, and his biography can not but invite and help others of like purpose.

The Pocket Encyclopedia for the Treatment of Disease in Children. By EDWARD FRYMANTER, M. D., Vienna, M. R. C. P. Lond., M. R. C. S., Eng., Clinical Assistant, Hospital for Sick Children, Great Ormond Street, etc. London: The Reuben Publishers' Company, Ltd., 1898. Pp. i+xx+208.

Although all formulae are fairly easy to use, the use of this little book, the name *Formulae*, is fairly self-explanatory, for its contents are formulae. The title is thereby implied. The book is divided into 10 chapters, on the plan of what is ordinarily known as a pharmacopoeia, and consists of a pharmacopoeia and a collection of the drugs useful in the diseases of the tropics. The chapters—and all of them are of considerable value—are: general, elementary, are arranged alphabetically, and are arranged successively to tell its contents, and the first chapter, on dose, and on pathology, is a very good introduction, and also useful formulae for the treatment of the various

given as the means for correcting ill taste. In an appendix are lists of drugs suitable for lotions, sprays, gargles, and the like, with the proper strength of solution indicated. A therapeutic index concludes the book, and in that, under headings of disorders, are listed the drugs useful for each. A not unimportant inclusion is a number of blank pages at the end of the book, on which additional data may be written as occasion arises.

The plan of the book, it will be seen, is eminently practical, and, since the choice of remedies is thoroughly good and the information concerning them well presented, it must be found useful in no ordinary degree.

A Text-book of Mechano-therapy (Massage and Medical Gymnastics). Especially prepared for the Use of Medical Students and Trained Nurses. By AXEL V. GRAFSTROM, B. Sc., M. D., Late House Physician, City Hospital, Blackwell's Island, etc. With Eleven Pen-and-Ink Sketches by the Author. New York: O. M. Fœgri & Co., 1898. Pp. 5 to 139.

A VERY satisfactory little work is this of Dr. Grafstrom's, and one which certainly fulfills its mission in rendering comprehensible the subjects of massage and medical gymnastics to medical minds other than those of specialists.

After a brief chapter of definition and classification, the effects of muscular action upon the body are taken up, and then there is a consideration of medical gymnastics in detail. These details cover the various parts of the body where gymnastic exercises are employed, and brief though complete directions are given for their performance. The practice of massage is next described in its several varieties.

To the medical man the concluding chapters, which discuss the therapeutics of massage and gymnastics, will naturally be of the greater interest, and in them there is much profit to be found. These chapters are much condensed, as are all the book contains; indeed, its brevity is its chief fault, and we could welcome a more extended treatise upon these subjects from Dr. Grafstrom, in view of the ability wherewith he handles his subject, and especially of the well-balanced conservatism he manifests in matters where enthusiasm is prone to be extravagant.

Handbook of Materia Medica for Trained Nurses. Including Sections on Therapeutics and Toxicology, and a Glossary of Terms with Dose and Use of each Drug. By JOHN E. GORF, Ph. C., Apothecary in the Rhode Island Hospital, Providence. Philadelphia: P. Blakiston's Son & Co., 1898. Pp. viii 9 to 235. [Price, \$1.25.]

This volume has been written for the purpose of instructing nurses in the nomenclature, the chemical structure, and the handling of drugs. It contains also a very complete glossary and an appendix on poisons and antidotes. The printing and binding are excellent, and it seems to be a very good text-book for the purpose for which it was written.

BOOKS, ETC., RECEIVED.

Thirty-fourth Annual Report of the Trustees of the Boston City Hospital, with Report of the Superintendent, the Medical and Surgical Statistics, House Rules, Rule for Admission, Discharge, and Government of Patient, a Prospectus of Training School for Nurses, etc. February 1, 1897, to January 31, 1898, inclusive.

Annual and Analytical Cyclopædia of Practical Medicine. By Charles E. de M. Sajous, M. D., and One Hundred Associate Editors, assisted by Corresponding Editors, Collaborators, and Correspondents. Illustrated with Chromolithographs, Engravings, and Maps. Volume II. Philadelphia, New York, and Chicago: The F. A. Davis Company, 1899. Pp. viii-667.

Les glycosuries non diabétiques. Par Germain Roque, Professeur agrégé à la Faculté de médecine, etc. Paris: J.-B. Baillière et fils, 1899. Pp. 5 to 92.

La pulsation du pied. Essai sur un nouveau signe clinique. Par le Docteur Silvio Tatti, Directeur du laboratoire de l'Hôpital Rivadavia, etc. Buenos Aires: J. Peuser, 1898. Pp. 3 to 44.

Il principio della dirigibilità orizzontale degli aerostati ed il binarostello. Mario Schiavone. Potenza: Garramone e Marchesio, 1898. Pp. 5 to 48.

Report of the Surgeon-General of the Army to the Secretary of War, for the Fiscal Year ending June 30, 1898.

Twenty-sixth Annual Report of the State Charities Association to the State Board of Charities of the State of New York. November 1, 1898. No. 70.

The American Medical Association: Its Past, Present, and Future. The Presidential Address. By N. Senn, M. D., of Chicago. [Reprinted from the *Journal of the American Medical Association*.]

Intestinal Tuberculosis: Etiology, Pathology, and Diagnosis; Surgical Treatment. By N. Senn, M. D. [Reprinted from the *Journal of the American Medical Association*.]

The Modern Treatment of Gunshot Wounds in Military Practice. By N. Senn, M. D. [Reprinted from the *Journal of the American Medical Association*.]

The Etiology and Classification of Cystitis. By N. Senn, M. D. [Reprinted from *International Clinics*.]

On the Frequency of Varicocele and the Limitations of Operative Treatment for this Affection. By N. Senn, M. D. [Reprinted from the *Philadelphia Medical Journal*.]

Edematous Changes in the Epithelium of the Cornea in a Case of Uveitis following Gonorrheal Ophthalmia. By Edward Sieren, M. D., of Pittsburgh. [Reprinted from the *Johns Hopkins Hospital Bulletin*.]

Odor as a Symptom of Disease. By J. H. McCassy, M. D., of Dayton, Ohio. [Reprinted from the *Medical Age*.]

The Milk Supply of Cities: Can it be Improved? By Henry O. Marey, M. D., of Boston. [Reprinted from the *Journal of the American Medical Association*.]

The Elimination of Bacteria from the General Circulation by the Liver and through the Bile Passages. A Claim for Priority in Stating the Presence of the *Bacillus typhi abdominalis* in the Gall Bladder. By Gustav Fütterer, M. D. [Reprinted from *Medicine*.]

How soon do Bacteria which Enter the Portal Vein become Disseminated throughout the System, and when does their Elimination Commence? By Gustav Fütterer, M. D. [Reprinted from *Medicine*.]

Primary Carcinoma of the Gall Bladder. By Gustav Fütterer, M. D. [Reprinted from *Medicine*.]

Ein Beitrag zur Frage der Übertragbarkeit von Warzen. Von Dr. Otto Lanz. [Separatdruck aus dem *Correspondenz-Blatt für Schweizer Aerzte*.]

Eine Beobachtung von Phlogococcus-Strangitis. Von Dr. Otto Lanz. [Separatdruck aus dem *Correspondenz-Blatt für Schweizer Aerzte*.]

Miscellany.

Salophene.—M. Creslé (*Gazette hebdomadaire de médecine et de chirurgie*, December 18, 1898), in a thesis before the faculty of Toulouse, considers salophene as now definitely settled in the therapeutic domain. It exerts, he says, an incontestable action upon acute and sub-acute rheumatism, but its effects are less constant than those of salicylate of sodium. In chronic and hemorrhagic rheumatism it has not shown itself superior to other drugs. Salophene possesses a powerful analgesic action which is exercised even in those cases where this drug can not be looked for to effect a cure. It has given good results in migraine, in various neuralgias, and in sciatica. Salophene employed in a medium dose produces no phenomena of intolerance, nor does it cause headache, buzzing in the ears, or troubles of vision, but tolerance appears to be rapidly induced. In certain cutaneous affections salophene appears to have some efficacy, but it is necessary to wait for further experience. The medium dose of salophene is sixty grains daily, more or less, according to the gravity of the complaint.

The Bacteriology of Erysipelas.—Dr. Leonard Freeman (*Colorado Medical Journal*, December, 1898) says that in every case of erysipelas, according to Unna, both the cutis and the subcutaneous tissues are involved, the latter more extensively even than the former, contrary to the usual teaching. The streptococci occupy primarily, and almost exclusively, the lymph spaces and vessels, invading the adjacent tissues in the more severe cases only. The lymph channels surrounding the larger blood-vessels of the hypoderm are favorite localities for the accumulation of bacteria, which, however, seldom if ever penetrate more deeply than the outer layers of the adventitia, although they have occasionally been found in the blood. Immense numbers are also found in the connective tissue and about the capillaries surrounding the fat lobules. In the hypoderm the cocci are more widely distributed, with less tendency to the formation of long chains than in the cutis; this being due, perhaps, to the fact that their growth in the former situation is more or less interfered with by the greater number of leucocytes. In the cutis the disease runs its course much more rapidly than in the subcutaneous tissues, so that microscopical sections of the skin made somewhat late during the course of the affection may show microorganisms in the hypoderm alone.

The changes in the blood-vessels are of prime importance, and serve to explain much that seems obscure. They are decidedly more pronounced in the cutis than in the subjacent tissues. In the cutis, the bacterial poisons, by their action upon the plasma of the blood, cause the formation of a rapidly coagulating fibrous substance which produces thrombi, particularly in the arterioles and capillaries. In the smaller veins, when thrombi appear, they are usually washed in from the capillaries. In the veins, however, the leucocytes become adherent in clumps, not along the walls of the vessel, but in the centre of the blood stream. The vessels become paralyzed, widened, and choked with red corpuscles, and stasis occurs. Although the number of leucocytes is considerably increased, and their vitality apparently unimpaired, there is comparatively little tendency to emigration through the vessel walls, owing to the extraordinary conditions just mentioned, and to the well-known feeble leucocytic powers of the streptococcus. Since the

cient numbers escape, however, to fill the normal lymph channels, but they seldom appear in any quantity in the surrounding tissues. Hence, in the cutis, we can not speak of a local leucocytosis. There is a marked exudation of fluid, due largely to venous stasis, which fills the lymph channels and escapes, in the more severe cases, into the intervening connective tissue. This at once coagulates, inclosing in its meshwork of fibres both leucocytes and cocci. In the subcutaneous tissues stasis is not so prominent a feature, and thrombosis seldom occurs, although there is free exudation and coagulation of fibrin, which extensively invades the fat lobules and their surrounding connective tissue. The migration of leucocytes, although more extensive than occurs in the cutis, is not a marked feature. Nevertheless large numbers of these corpuscles are found in the lymph channels around the larger vessels, in the connective tissue between the fat lobules, and, in fact, distributed more or less generally throughout the tissues. This is accounted for by the fact that a considerable proportion of the leucocytes is brought from the cutis through lymph channels which end in the hypoderm.

In cases of simple erysipelas this "leucocytosis" disappears without making itself macroscopically evident; but where the inflammation is more severe suppuration manifests itself, although it is not so profuse as when a mixed infection with staphylococci is present, or when a staphylococcus infection alone exists. Streaks of purulent material form in the septa between the fat lobules, composed of a mass of leucocytes, liberated fat and protoplasm, cocci and fibrin.

Much discussion has taken place regarding the mutual relations between leucocytes and cocci. Metschnikoff and his followers believe that a "battle" is waged between the cells and the bacteria. When the former become the victors the cocci are "swallowed" and killed; when the latter conquer, the leucocytes become disintegrated. Baumgarten and others have strongly combated this theory, and the majority of facts seem to be upon their side. If Metschnikoff's idea is correct, we should expect to find the advance of the streptococci met by a wall of leucocytes, as in a staphylococcus inflammation; but this is not the case. The bacteria spread on in advance, and the so-called phagocytes bring up the rear. In fact, a "wall" of cocci is often seen surrounding a mass of leucocytes. According to Unna, the occasional presence of bacteria within the bodies of the leucocytes necessarily means neither the death of the cocci nor the disintegration of the corpuscles. The streptococci, on the other hand, perish in great numbers over large areas whether leucocytes are present or not, "the conquerors often dying in the midst of the conquered," their death being due, probably, to the saturation of the diseased tissue with poisons. In like manner, the degeneration of large numbers of leucocytes may take place without the direct intervention of microorganisms. As regards the cutis alone, there can be no doubt that in this there is no local leucocytosis, and no metastream, where leucocytes exist in great numbers the streptococci seem to thrive best.

Since the migration of leucocytes, as Koch, it has been almost universally held, is toward the center of the "red zone," and since cocci are found in considerable numbers in the outer borders of the "red zone" only, it is not surprising that especially toward the center of the "red zone" a few cocci are found. According to the same author, to a certain extent of the cutis, the leucocytes are found to find numbers of leucocytes in the metastream.

tainly not hold good where the hypoderm is concerned, for in this region swarms of streptococci exist everywhere.

From a histological standpoint, degenerative changes of two kinds may take place—softening and coagulation. They are due to the action of bacterial poisons and to thrombosis within the blood-vessels. If the disease is sufficiently active, degeneration may end in the production of a mushy necrotic mass, which occurs, however, in limited areas only. In coagulation the entire connective tissue seems to become transformed into a fibrinous network, inclosing bacteria and leucocytes, and resembling a diphtheritic membrane.

Vesicles are formed by the separation of the epithelium from the papillary layer of the skin; seldom if ever by liquefaction of the epithelium itself, as claimed by Wagner. The vesicles contain numerous leucocytes and considerable fibrin, but cocci are seldom found. Curiously enough, the deep epithelium, and that in connection with the glandular structures, suffer less than the superficial.

Phegmonous erysipelas does not differ essentially from the ordinary form. In fact, every simple erysipelas is essentially "phegmonous" in that the subcutaneous tissues are filled with leucocytes, although pus may not be macroscopically evident. Much depends upon the resistance of the tissues and the virulence of the cocci, factors which vary considerably in different cases, as has been emphasized by Petruschky. This does not exclude the possibility of a mixed infection with staphylococci, especially in cases of profuse suppuration. Staphylococci alone, however, can not cause an extensive spreading suppuration any more than they can cause an erysipelas.

Progressive phegmonous inflammations, with edema, extensive suppuration and sepsis, but without redness of the skin, are probably erysipelatous in their nature and caused by the same micro-organism. The virulence of the infective process is such that extensive thrombosis of the blood-vessels of the cutis results, effectually preventing the redness so characteristic of ordinary erysipelas. For the same reason, necrosis of the skin is apt to supervene.

Sporadic elephantiasis nostras is closely related to erysipelas. Repeated attacks of the latter disease cause circulatory disturbances which prevent complete resorption. A certain number of streptococci seem to remain more or less permanently within the tissues. The process is similar, in some respects, to so-called chronic erysipelas.

To epitomize: Typical erysipelas of the cutis is a simple sero-fibrinous inflammation, which may result in necrosis. In the subcutaneous tissues the disease is apt to become fibro-purulent, owing to the accumulation of leucocytes having their origin in both derm and hypoderm.

"Tips" for Practitioners. Dr. William Murrell, of the Westminster Hospital, London (*Medical Brief*, January), in an article on The American Physician in London, says that he endeavors to impress upon his students the importance of

1. The value of small doses of tincture of acetate of iron frequently repeated in the treatment of amygdalitis and in the initial stage of febrile disease.

2. The value of painting the chest and back with *Rhine oil* (diluted if necessary with an equal quantity of the tincture) in all cases attended with cough.

3. The value of a pill of exsiccated ferrous sulphate in conjunction with the administration of purgatives in the treatment of anæmia.

4. The value of grain doses of gray powder with an equal quantity of Dover's powder from three to six times a day in the treatment of syphilis.

5. The value of large doses of the iodides in the treatment of tertiary syphilis.

6. The value of large doses of bromide of potassium in the treatment of the "heats and flushes" and other symptoms from which women suffer about the time of the menopause.

7. The value of large doses of quinine in the treatment of supraorbital neuralgia, and in the periodical febrile disturbances from which old malarial patients suffer.

8. The value of five grains of butyl-chloral-hydrate with one two-hundredth of a grain of gelsemin in neuralgia of the fifth nerve.

9. The value of small doses of a saturated solution of camphor in alcohol in the treatment of autumnal or choleraic diarrhæa.

10. The value of small doses of perchloride of mercury in the treatment of infantile diarrhæa when the stools are green, slimy, and offensive.

11. The value of sulphide of calcium in doses of a tenth of a grain in the treatment of boils, carbuncles, and abscesses.

12. The value of nitroglycerin and nitrite of amyl in the treatment of angina pectoris and allied conditions.

13. The value of alcohol in the treatment of fevers.

14. The value of flying blisters in typhoidal conditions.

The Influence of Barometrical Pressure on Disease.

—The *Clinique* for September 15th quotes the following from a paper by Dr. T. Wesley Burwood published in the *Monthly Homœopathic Review* of London. We reproduce it, because we ourselves have more than once been engaged on a similar train of thought, and are satisfied that a careful study of barometrical pressure in relation to the ups and downs of disease, especially in chronic cases, by physicians would elucidate in time some very important factors, and would, moreover, give the physician material assistance in dealing with many peculiar cases. Dr. Burwood says:

"Toward the end of the month of January, 1882, I was brought face to face with a puzzle which gave me much personal chagrin, though it eventually has proved a source of much satisfaction, as it opened up a line of thought which to me has been very useful.

"I had been in regular attendance on a gentleman whose name is well known. He had been my patient off and on for some years for trivial ailments, and I flattered myself I knew everything it was possible to know about him; he had been a most healthy man, never having had a serious illness since childhood. His habits were those of an English gentleman, and until a few months before his death he might have been seen on horseback in 'the Row' every morning of his life when in London. He, however, toward the end showed signs of oedema in the feet due to heart trouble. There was no valvular lesion, though latterly marked dilatation was evident. There was no albumin in his urine and his present condition might be summed up as due to old age (eighty-four).

"I had seen him one day about 6 p. m.; he was jolly

Some Remedies with Fanciful Names.—In the *Dominion Medical Journal* for October there is a list, under the heading of Recent Synthetic Remedies, which, with some additions of our own (distinguished by the names being printed in italics), is substantially as follows:

Acetol.—A name given to silver lactate, which is recommended like itrol (silver citrate) as an antiseptic in gonorrhoea and gonorrhoeal ophthalmia.

Agathin — $C_6H_4.OH.CH.NN.CH_3.C_6H_5$ — Sali-cyl-*a*-methyl-phenyl-hydrazone. Antirrhematic.

Airol — $C_6H_5(OH)_4.CO_2BiI$ — Bismuthoxy-iodo-gallate. Antiseptic.

Alpha-eigon.—An iodine compound of albumin, containing twenty per cent. of albumin. Alpha-eigon-sodium is the sodium compound, soluble in water, and containing fifteen per cent. of iodine. Beta-eigon is an iodine-peptone compound.

Alumol. Aluminum naphtho-sulphonate. Astringent. Antiseptic.

Analgen — $C_9H_5(OC_2H_5)NH(CO.C_6H_5)N$ — Ortho-ethoxy-ana-mono-benzoyl-amidoquinoline. Antipyretic. Analgetic.

Antiliprine.—Obtained by melting together one part of acetanilide and two parts of antipyrine. It is fairly soluble in water, and is stated to have given good results in influenza, rheumatism, etc. The dose is from five to fifteen grains, two or three times a day.

Antiscabine.—A mixture of Peruvian balsam, Castile soap, glycerin, beta-naphthol, boric acid, and alcohol. Introduced as a remedy for scabies, to be applied two or three times a day.

Antiseptol. Cinchonine iodosulphate. Antiseptic.

Anglin.—A thirty-three-per-cent. aqueous solution of ichthyl-sulphonic acid, one of the principal constituents of ichthylol. Recommended in dermatological practice.

Argentamine.—An amido-compound of silver. It has been recommended as a substitute for nitrate of silver, being less irritating and a superior antiseptic, in conjunctival diseases.

Argonin. Silver caseinate. Antiseptic.

Aristol — $C_6H_4.CH_3.OI.C_3H_7)_2$ — Di-thymol-di-iodide. Antiseptic.

Asaprol — $CaC_{20}H_{14}S_2O_8 + 3H_2O$ — Calcium-beta-naphthol-sulphonate. Antirrhematic. Antituberculous.

Asseptol — $C_6H_5(OH)SO_3H$ — Phenol-sulphonic acid.

Benzosol — $C_6H_5(OC_2H_5)OC_6H_5CO$ — Benzoyl-guaiaacol. Antituberculous. Antiseptic.

Bismal — $H_3H_2O_9.3Bi(OH)_3$ — Bismuth methyl-ene-digallate. Astringent.

Bromol — $C_6H_4Br.O.H$ — Tri-bromo-phenol. Antiseptic and disinfectant.

Captol.—A condensation product of tannic acid and chloral. It is a dark-brown hygroscopic powder, slightly soluble in cold, more soluble in warm water and in alcohol. Recommended as an antiseptic astringent in the treatment of falling of the hair from seborrhoea, etc.

Chloralamide — $C_2H_5O.C_2H_5N$ — Chloral formamide. Hypnotic and analgetic.

Citruin. A compound (probably a mixture) of citric acid, urea, and lithium bromide, said to be useful when the effect of urea and lithium is desired.

Cresdin. Coal, colcoed, and colcol are more or less impure forms of mixture obtained from coal tar.

Crocol — $C_2H_5CH_2(OC_2H_5)OH$ — Homo pyro-catechin mono-methyl-ether. Antiseptic.

Dermatol — $Bi(OH)_2C_2H_5O_5$ — Bismuth subgallate. Astringent. Antiseptic.

Diuretin — $C_8H_7N_3O_2.Na + C_6H_4(OH)CO_2N$ — Theobromine-sodium-sali-cylate. Diuretic.

Durol — $C_6H_2CH_3CH_3CH_3CH_3$ — Tetra-methyl-benzol.

Eucaine hydrochloride — $C_{10}H_{27}NO_4.HCl + H_2O$ — Benzoyl-methyl-tetra-methyl- γ -oxy-tetra-piperidine-carbonic-methyl-ester hydrochloride. Local anæsthetic.

Euphthalmine Hydrochloride.—The amygdalic acid derivative of methyl-vinyl-diacetone alkaline, $C_{17}H_{25}NO_3.HCl$. It is colorless, crystalline, and freely soluble in water. It has a powerful mydriatic action in five- or ten-per-cent. solutions. It is asserted that its action is superior to that of homatropine.

Eurobin.—A compound of chrysarobin and acetic acid, apparently an acetate of that body, introduced as superior to chrysarobin in dermatitis, etc.

Europhene — $C_8H_9(CO_2)(O)C_6H_3C_2H_5.OI.CH_3$ — Iso-butyl ortho-cresol-iodide. Antiseptic. Antisyphilitic.

Ferrosol.—A double compound of ferric saccharate and saccharate of sodium chloride. It is a clear, dark-black liquid, strongly ferruginous and saline. Recommended in chlorosis and anæmia, in teaspoonful doses three times a day.

Gaiacyl.—The calcium salt of guaiacol sulphonic acid. It occurs as a grayish-violet powder, soluble in water and in alcohol, insoluble in oils. It is employed as a local anæsthetic in five- or ten-per-cent. solutions.

Gelante.—A new dressing recommended by Unna, prepared from tragacanth and gelatin, with the addition of a little glycerin, rose water, and a trace of thymol. Various antiseptic medicaments can be added.

Gcosote.—Guaiacol valerianate. It is an oily liquid, with a sweetish taste, and has been recommended in pulmonary catarrh, and injected subcutaneously in tuberculous glands or joints.

Guaethol or *Guithol*.—A derivative of guaiacol in which the methyl group is replaced by ethyl. It is an oily liquid, and has an aromatic odor. Its analgetic action is stated to be superior to that of guaiacol; it is used as an ointment, one part to six of vaseline.

Guaiaacol Carbonate — $C_6H_4(OCH_3)_2CO_3$ — Guaiaacol-ester carbonate. Antituberculous antiseptic.

Guaiaacol, synthetic — $C_6H_4(COH)COH_5$ — Pyrocatechin-methyl-ether. Antituberculous antiseptic.

Guaiaquin.—Obtained by the action of guaiacol-sulphonic acid on quinine. It occurs as a yellow odorless powder, with an acid bitter taste, readily soluble in water, alcohol, or acids. Recommended in anæmia, malarial disease, etc.

Heliotropine. Piperonal. Proto-catechu-aldehyde-methyl-ester. Antiseptic. Antipyretic. Used in perfumery.

Hypnal — $CCl_3CH(OH)_2C_{11}H_{12}N_2O$ — Chloral-hydrate-antipyrine. Analgetic. Antipyretic.

Hypnone — $C_6H_5CO.C_2H_5$ — Phenyl-methyl-ketone-aceto-phenone. Hypnotic.

Iodol — C_4H_7NI — Tetra-iodo-pyrrol. Antiseptic.

Irol — $Ag_2C_6H_5O_5$ — Silver citrate. Antiseptic in treatment of wounds.

Lactophenine — $C_6H_4(OC_2H_5)NH.CO.CH(OH).CH$ — Lactyl-amide phenol-ethyl-ether.

Lacto somatose. A compound of somatose and desiccated milk, asserted to be a strength-giving food, containing the albuminous matter of milk.

Loretin — $C_9H_9NI \cdot OH \cdot SO_3H$ — Ortho-oxyquinoline- μ -iodo-ana-sulphonate. Antiseptic.

Losophane — $C_6H_3 \cdot OH \cdot CH_3$ — Tri-iodo-meta-cresol. Astringent. Antiseptic.

Lycetol. Dimethyl-piperazine-tartrate. Analgetic. Diuretic.

Lysidine — $(C_2H_5)_2NH \cdot N \cdot C \cdot CH_3$ — Methyl-dihydro-glyoxaline uric acid. Solvent.

Malakin — $C_7H_5O_2N$ — Salicyl-amido-phenol-ethyl ether. Antiseptic. Analgetic.

Microidin. Sodium beta-naphtholate. Used in antiseptic surgery.

Mydrin.—A combination of ephedrine hydrochloride and homatropine, used for dilating the pupil. It is said that a ten-per-cent. aqueous solution causes mydriasis quickly, without affecting accommodation or causing discomfort.

Nosophene — $(C_6H_4I \cdot OH)_2 \cdot C \cdot C_6H_4CO \cdot O$ — Iodo-phenene. Tetra-iodo-phenol-phthalein. Antiseptic. Disinfectant.

Orthoform. Para-amido- μ -oxy-benzoic-methyl ester. Local anæsthetic.

Ossalin.—A fat prepared from fresh bone marrow, resembling lanolin in its property of absorbing water. It is neutral, grayish, and has the odor of tallow. Recommended as an ointment basis.

Peronine — $C_{17}H_{15}NO_2 \cdot O \cdot C_6H_5 \cdot CH_2 \cdot HCl$ — Benzyl-morphine-hydrochloride. Narcotic.

Phenocoll Hydrochloride— $C_6H_4(OC_2H_5)(NHCO \cdot CH_2NH_2)HCl$ — Amido-acet-phenetidine-hydrochloride. Analgetic. Antirheumatic.

Piperazine — $C_2H_4(NH_2)C_2H_4$ — Diethylene-diamine. Antirheumatic.

Piperonal. Heliotropine, which see.

Protargol.—A fine yellowish powder consisting of silver combined with a protein substance, and containing 8.3 per cent. of the metal. It is soluble in water, and the solution does not stain the skin or cause irritation, like most other silver salts. It possesses marked bactericidal properties; for injections, one-fourth to one-and-a-half-per-cent. solutions are used.

Pyrosal.—The salicyl-acetate of antipyrine. It is soluble in water and recommended as an antirheumatic and antineuralgic, in doses of from five to ten grains.

Resoreinol. Iodoform and resorein. Antiseptic dressing.

Salacetol — $C_6H_4(OH) \cdot COO \cdot CH_2 \cdot O \cdot CH_3$ — Acetyl-salicylic-ester. Antiseptic. Antirheumatic.

Salpyrine— $C_{11}H_9N_2O_2 \cdot C_2H_5O_2$ —Antipyrine salicylate. Antipyretic. Analgetic.

Salophene — $C_6H_4OH \cdot COO \cdot C_6H_4N \cdot H \cdot COCH_3$ — Acetyl-para-amido-sal. Antiseptic. Antipyretic.

Symphoral $N \cdot C_6H_4N_2O_2 \cdot SO_3Na$ —Caffeine sodium sulphate. Diuretic. There are also lithium and strontium salts.

Tannalbin. Tannin albuminate. Astringent.

Tannin, or Tannopine. —A condensation product of tannin and hexamethylenetetramine or urotropin $6(CH_2)_4N_4(C_6H_4H_2O_2)_2$. It is a light brown powder, free from taste or odor, insoluble in water or alcohol. Recommended as an intestinal-astringent, especially in tuberculosis, enteritis and typhus.

Tinnygen. —A compound of acetic acid and tannin. An intestinal astringent, and most efficacious in chronic, acute, and summer diarrhoeas. Dose for an adult, 10 grains every three hours.

Terpinol ($C_{10}H_{12}$) H_2O Terpin hydrate. Disinfective. Used in bronchial affections and in perfumery.

Tetronal — $(C_2H_5)_2 \cdot C(C_2H_5SO_2)_2$ — Di-ethyl-sulphon-diethyl-methane. Hypnotic and sedative.

Thalline Sulphate — $(C_{10}H_{15}NO)_2H_2SO_4$ — Tetrahydro-paraquinamisol sulphate. Haemostatic and antiseptic.

Thermodine — $C_6H_4(C_2H_5O)NCO \cdot C_6H_4COCH_3$ — Acetyl- π -ethoxy-phenyl-urethane. Antipyretic. Antiseptic.

Thiocol.—The potassium salt of guaiacol-sulphonic acid, $C_6H_3OH \cdot O \cdot CH_2 \cdot SO_3K$, and containing about sixty per cent. of guaiacol. It is a fine white powder, with a bitter-sweet taste, soluble in water, recommended as a substitute for guaiacol.

Triphenine — $C_6H_5OC_2H_5NHC_2H_5CO$ — Propionyl-phenetidine. Analgetic. Antipyretic.

Validol.—A combination of menthol and valerianic acid with an excess of menthol. It is a colorless fluid, possessing powerful stomachic and carminative properties. The dose is from ten to fifteen drops, either on sugar or in wine.

The Death of Sir James Mouat.—The death, at the age of eighty-three years, is announced in the *British Medical Journal* for January 14th of Surgeon-General Sir James Mouat, K. C. B., V. C., honorary surgeon to Queen Victoria, and a distinguished British military medical officer.

The Argumentum ad Feminam in "Christian Science."—The *British Medical Journal* for January 14th, commenting on Mrs. Eddy's recent pastoral, says:

"The high priestess of Christian Science, who surpasses Miss Marie Corelli in her gift of uttering ineptitudes with an air of inspiration, says loftily that 'a person's ignorance of Christian Science is a sufficient reason for his silence on the subject.' We cheerfully admit as a general principle that no one should speak of what he does not know, but we take leave to suggest to Mrs. Eddy that she would do well to hear this sound principle in mind when she feels a moving of the spirit to deliver her views on the treatment of disease. When she asks, 'What can atone for the vulgar denunciation of what a man knows absolutely nothing about?' we venture to ask in turn, 'What more are we expected to know about Christian Science than Mrs. Eddy has set forth in her book?' If the world does not now know all that there is to be known about Christian Science, the fault is Mrs. Eddy's own."

A System of Thieving in the School of Medicine of Columbia University is said to have been brought to light recently, and to have resulted thus far in the expulsion of one of the students. The articles stolen were instruments and chemicals.

Weyler's Fever.—We hear frequently of diseases which are named after their first investigator, such as Addison's disease, Bright's disease, etc. but we have not heard of *la Fiebre de Weyler* of Havana for many years. It is said that among the diseases which dominated the island of Cuba was "a grave form of paludism, characterized by chronic anemia, terminating, or at least leading to, and named Weyler's fever."

Extraordinary Case of Placenta Prævia.—M. B. Lot and M. Miravalles report a case in the *Boletín de la Academia de Medicina de Cuba*, January 31st, 1898. The patient, a woman, twenty-five years of age, had been married

was found to occupy the entire area of the dilated uterine os. The only course open was to penetrate through the placenta and perform podalic version, which was accordingly done. There was very little hemorrhage, and the placenta was expelled soon after the extraction of the child, which appeared to be dead. After fifty-five minutes of artificial respiration, mouth-to-mouth insufflation, hot cloths, etc., the child was brought to life. The examination of the placenta showed that it was complete, and that the child had been born through an opening made in it and situated about two inches and three quarters from its centre, to which the cord was attached. There were no accidents consequent on the accouchement.

A Yearbook of Neurology and Psychiatry is announced, according to *Science* for January 13th, by S. Karger, Berlin, edited by Dr. Flatau and Dr. Jacobsohn, under the direction of Professor Mendel. The work is prepared with the cooperation of a large number of leading German neurologists, and will perform a useful function, owing to the wide dispersion in many journals of publications on the subjects included. It will give not only a bibliography of some thirty-five hundred titles of the literature of 1897, but also short reviews of their contents.

A New Medical Journal in Kansas.—We learn that the *Kansas Medical Journal*, which has been published in Topeka for the last ten years, has been discontinued, and that its former editor, Dr. W. E. McVey, will have editorial control of the *Medical Monograph*, which is to be a monthly of a hundred and fifty pages.

The Annals of Ophthalmology.—We learn that Dr. H. V. Wündermann, of Milwaukee, who has been associate editor in charge of the department of German literature, has accepted the position of editor in chief, *vice* Dr. Casey A. Wood, of Chicago, resigned. Dr. Wood will remain in charge of the department of Italian literature. The staff will shortly be enlarged by the appointment of six collaborators. Abstracts of Dutch, Russian, Scandinavian, Polish, and Greek literature will hereafter be included.

The New York Academy of Medicine.—At a stated meeting, on Thursday evening, the 2d inst., Dr. Louis L. Seaman read a paper entitled the United States Army Bacterium and its Adaptability for Use in Tropical Climates, which was discussed by Major J. M. G. Woodbury, Colonel Charles R. Greenleaf, Dr. A. H. Smith, Dr. Charles H. Shepard, Major H. S. Kilbourn, Major W. D. Bell, Major N. S. Jarvis, Brigadier-General Eugene Griffin, and others.

At the next meeting of the Section in Pediatrics, on Thursday evening, the 5th inst., Dr. B. Scharlan will read a paper on Deformal's Operation for Chronic Emphysema, which is to be discussed by Dr. Robert F. Weir, Dr. A. G. Gersdor, and Dr. Willy Meyer. Patients were presented and specimens and new instruments were exhibited.

The Eastern Section of the American Laryngological, Rhinological, and Otolological Society. The annual meeting was held in Washington, on Saturday, January 25th, under the presidency of Dr. Charles W. Richardson, of Worcester. In addition to the president's address, six papers were presented: Reflex Cough, by Dr. George L. Richards, of Fall River, Massachusetts; Laryngeal Lesions in Operative Procedures

in Staphylothyph, by Dr. John C. Lester, of Brooklyn; The Proper Point of Incision in Peritonsillar Abscess, by Dr. Norval H. Pierce, of Chicago; Adenoid Vegetations of the Nasopharynx, by Dr. John O. McReynolds, of Dallas, Texas; Chorea of the Larynx, with a Report of a Case, by Dr. Joseph A. Stucky, of Lexington, Kentucky; An Unusual Case of Sinus Thrombosis and Epidural Abscess, complicated by Malaria, by Dr. M. D. Lederman; Two Operations for Mastoiditis with Unusual Features, by Dr. Thomas R. Pooley; The Simplest Non-operative Treatment of Otorrhoea, by Dr. Arthur G. Hobbs, of Atlanta; The Rebuilding of a Nose without the Insertion of an Artificial Bridge, by Dr. T. Passmore Berens; A Case of Self-inflicted Wounds to both Ears, both Eyes, and Larynx, by Dr. George Reuling, of Baltimore; The Necessity for Antiseptic and Aseptic Methods of Surgery of the Ear, Nose, and Throat, by Dr. Woolsey Hopkins; A Report of an Interesting Case of Dyspnoea in an Adult, by Dr. Walter B. Johnson, of Paterson, N. J.; a paper on The Operative Treatment of Chronic Purulent Otitis was discussed by Dr. Edward Dench, Dr. J. F. McKernon, Dr. S. Macuen Smith, of Philadelphia, Dr. Frederick L. Jack, of Boston, Dr. J. A. White, of Richmond, and others.

The American Orthopaedic Association.—The thirteenth annual meeting will be held in New York, on Wednesday, May 31st, and Thursday and Friday, June 1st and 2d, under the presidency of Dr. W. R. Townsend.

The Law of Compensation.—*Medical Snap Shots* states in its issue for February that "a physician, in speaking of the business side of the practice of medicine, says: 'A doctor will trust people longer and more foolishly than any man on earth. He will go on trusting people for years, until they leave him on account of hating him because they have owed him so much and so long. Then they will go to another physician and pay him, with little or no hesitancy.'"

The American Medical Association.—At the Columbus meeting, in June, in addition to their regular programmes, the Section in Ophthalmology and the Section in Laryngology and Otolology will devote the morning of the second day, June 7th, to a joint meeting, under the chairmanship of Dr. Casey A. Wood, of Chicago, and of Dr. Emil Mayer, of New York. The subject for discussion will be The Relation of Ocular Diseases to Affections of the Nose and Neighboring Cavities. Four papers are to be read on this subject, by invitation, as follows: Dr. Charles Siedman Bull, of New York, on Some Points in the Symptomatology, Pathology, and Treatment of the Sinuses Adjacent and Accessory to the Orbit; Dr. D. Bryson Delavan, of New York, on Nasal Stenoses in their Relation to Ocular Disturbances; Dr. Joseph A. White, of Richmond, Virginia, on Eye Troubles Attributable to Nasopharyngeal and Aural Disturbances; Dr. J. H. Bryan, of Washington, D. C., on Diseases of the Accessory Sinuses in their Relation to Diseases of the Eye. The general discussion will be on the main question.

The Southern Medical Journal is the title of a new octavo monthly of twenty-eight pages, edited by Dr. J. W. P. Smithwick, of La Grange, North Carolina, where it appears to be published, although it is printed in Kinston.

Original Communications.

FUNCTIONAL NEUROSES

AND THEIR RELATION TO
THE DISEASES PECULIAR TO WOMEN.*

By H. J. BOLDT, M.D.,

PROFESSOR OF GYNECOLOGY IN THE POST-GRADUATE MEDICAL SCHOOL;
GYNECOLOGIST TO THE POST-GRADUATE HOSPITAL;
TO ST. MARK'S HOSPITAL, AND TO THE GERMAN POLIKLINIK;
AND CONSULTING GYNECOLOGIST TO BETH ISRAEL HOSPITAL.

OF all patients who come under the observation of the gynecologist those having neuroses require the greatest care and judgment as to cause and effect, if the treatment is to be successful. I will state that in my theme I do not include the conditions ordinarily considered as true neuroses—as, for example, vaginismus dependent upon hypersensitiveness of hymenal remnants, or coealgodynia dependent upon an injury sustained during childbirth—but shall consider only those which may be called purely reflex. Experience has taught us that the physiological functions of the female genitals can influence the nervous system, and that, consequently, pathological conditions of them are frequently productive of neuropathic states. It may be possible, too, for diseases of the nervous system to produce symptoms which seem to arise from the pelvic organs, and which simulate disease of the latter, but I can not concede the possibility that such neurological state can produce an actual pathological condition of the genitals, as has been asserted by some authors. If we bear in mind the bountiful nerve supply of the genital organs from the great sympathetic through the hypogastric plexus, and from the cord through the internal pubic, sufficient reason can be found for the causation of reflex neuroses.

I look upon functional neuroses as a depraved condition of the nerve substance, which can not be demonstrated anatomically. The late Professor John T. Darby defined the condition as a starvation of the nerves, central and peripheral.

It is not my intention to dwell upon the complex structure of the nervous system, and I shall therefore limit myself to some practical points.

Some neuropathologists hold the view that all functional neuroses arise on a neuropathic basis, deny all other aetiological moments; older gynecologists attributed all to diseases of the sexual organs, and defined them as reflex neuroses. Both views are extreme; the correct position is the middle line.

A woman who is hereditarily predisposed to hysteria is more apt to develop it if she becomes subject to an affection of the genital organs than one in whom the hereditary element is excluded, showing that the genital organs play an important role in the production of neuroses.

The observation that neuroses and pelvic disease occur more frequently in our time than in former generations is accounted for by various factors. Many neuroses are dependent upon early training, a subject to which too much attention can not be devoted, especially about the time of puberty. Gross negligence must be charged to many parents in not paying attention to the effect of severe mental strain upon weak and delicate girls at this time. They are crowded on and on, until menstrual disturbances are manifested and a chlorotic neurasthenic constitution is presented—an intellectual training achieved at the expense of physical development.

The manner of dress is worthy of more thought by the medical adviser than is usually given it; young women frequently impede the development of the chest and abdominal organs by tight waistbands and corsets; impediment of the circulation in the lower extremities is caused by tight garters; faulty position of the pelvis in walking, by misplaced and too high heels in footwear. Habitual constipation and overdistention of the bladder contribute to the production of pathological pelvic conditions by causing temporary changes in the pelvic circulation, which in time may lead to chronic inflammatory changes.

Let us for a moment view one of the most common neuroses of woman—namely, hysteria—which may be termed a cerebral neurosis. To develop such an affection of the brain a proper soil is necessary, as under perfectly normal conditions its development is impossible; the predisposing soil being placed in the brain through heredity, physical or mental exertion, psychical disturbances, overindulgence in alcoholic beverages, and the physiological functions and diseases of the generative organs. For instance, the off-spring of a neurotic mother sustains during confinement a laceration of the cervix, which is of such extent as to leave cicatricial tissue in the vaginal vault and the portio vaginalis; the tear remains non-coapted and an erosion makes its appearance; an endocervicitis and subsequently an endometritis follows, the uterus remains large, and she has a sensation of weight in the pelvis; menstruation is prolonged and profuse, perhaps irregular; backache and neuralgia are present as concomitant symptoms; gradually a train of nervous symptoms is developed, showing themselves in irritability of temper, headache, and loss of appetite, and eventually the typical picture of a hysterical person is produced. Here, then, we have a reflex functional neurosis, dependent primarily upon changes in sustained during childbirth. If the same woman is unable to develop this condition if the same is exposed to enter the straits for an extended time. Nature has not endowed woman with a hereditary constitution of opposite sex, and a child of opposite sex is not exposed to the same strain as a woman. Puerperal psychosis, neurasthenia, alcoholism, etc., are not hereditary conditions.

* Read before the Section in Obstetrics and Gynecology of the New York Academy of Medicine in October, 1898.

functional neuroses—as, for example, the sudden death of a near relative under the adverse circumstances last alluded to.

It is not only difficult but impossible for one to determine how much influence a coexisting pelvic abnormality has on the respective neurosis until such patient has been under treatment for some time. It is obvious, then, that a physician in dealing with neuroses should have an eye on the social position of the patient, considering her duties in life, her hygienic surroundings, etc.

Among particular forms of reflex neuroses, those in connection with menstruation are quite prominent—as, for example, acne rosacea, eczema, urticaria, etc. The following instance is unusual:

A girl, aged fourteen years, began to menstruate between the eleventh and twelfth year; the flow was profuse, and of eight days' duration. A few months after the appearance of the menstrual epoch the child developed an eczema which extended over the hips, buttocks, and posterior surface of the thighs, gradually diminishing to nearly complete disappearance for two weeks after cessation of the flow. Upon the recurrence of each menstrual flow, the skin affection was intensified and took a similar course as on previous occasions. The writer was finally consulted on account of the exceedingly profuse flow. The child was well developed, short in height, and very plump. She complained of great weakness and was very anæmic, the quantity of hæmoglobin being reduced to forty-five per cent. A recto-abdominal examination revealed no pathological condition to account for the profuse bleeding. Incidentally my attention had also been called to the eczema. The girl was placed upon the use of stypticin in doses of a quarter of a grain every three hours, beginning four days prior to the next period, and with the beginning of the flow the dose was increased to half a grain every two hours. The result was that the next period continued only five days, the loss of blood was greatly diminished, and the eczema not intensified at this period. The treatment was continued three months, the flow diminishing to three days' duration, and of moderate quantity; the anæmia disappeared, and the eczema vanished completely without any direct treatment.

Another remarkable instance of menstrual neurosis was that of a girl seen by me in 1885, and reported in the *American Journal of Obstetrics* for February, 1886, as a case of reflex vasomotor neurosis dependent on a displaced ovary. The case is, I believe, unique. I have been unable to find any resemblance to it in the multitude of material observed before and since then. The chief features were that with the first appearance of the flow at the age of thirteen years the girl noticed a purple discoloration of the right upper extremity, interwoven with white spots the size of a lentil, and a swelling on the right leg and foot without discoloration was manifest at the same time.

During each menstrual period the upper extremity felt cold, the change in sensation beginning one day prior to the flow and reaching its height on the fifth day. In addition to this cold feeling she had on the three occasions when the discoloration was noticed a feeling of formication in the entire upper extremity.

When seen by me there were decided differences in the menorrhagia between the right and left side, and the superficial venous and capillary of the affected side,

as well as the veins of the anterior surface of the thorax, were greatly distended.

The severe pain in the right inguinal region, principally during the menstrual period, for which the patient came for advice, was considered to be due to an enlarged prolapsed right ovary. The girl was entirely cured of the dysmenorrhœa, and with it the neurosis also disappeared, so far as I know from about four years' occasional observation of the patient, subsequent to the conclusion of treatment.

Various forms and degrees of skin lesions in direct connection with menstruation have been observed by many, but the two instances alluded to above are the most interesting cases of undoubted pure functional dermatological neuroses which have come under my observation.

Among another class of functional neuroses dependent upon the menstrual period the psychoses melancholia and hypochondriasis occurring during the menopause are most important. Anatomically speaking, these conditions can not be classed among diseases based upon pathological changes; the best reason for classing them under the nomenclature discussed being that, in the majority of instances, the neurosis disappears in a year or two after the climacteric age has been passed.

What else than a reflex neurosis dependent upon changes in the pelvic organs can we term the anæmic and neurotic state occasionally observed in instances of formerly perfectly robust and healthy girls, who have been so unfortunate as to become a prey to seduction with consequent illegitimate pregnancy? I remember having seen two such instances in girls who changed as if by magic when they became joined in lawful wedlock to their respective seducers before the termination of gestation.

The neuroses of pregnancy, the puerperal and lactation psychoses, and their relation to the conditions mentioned, are no longer a mooted point, and to discuss them on this occasion would take up more time than is permissible to-night.

It has been denied by some that the non-satisfying of the sexual desire is ever productive of neuroses. Such assertion must, however, not be looked upon seriously, but rather as coming from a would-be reformer of human morals. Cardialgia, temporary tachycardia, cephalalgia, and general malaise, often associated with anæmia, are frequently found connected with menstrual disturbances due to an endometritis, and in a few instances I have had every reason to attribute these symptoms to the desire alluded to. In the case of one person, who had been under my observation for two years, all the reflex symptoms which were present disappeared within six months after her marriage.

The neurotic conditions associated with true nymphomania are too well recognized by the majority of physicians to require more than passing mention; I have seen one instance completely cured by the removal of an hypertrophied clitoris; on the other hand, however, sev-

eral failures after the operation have also been recorded by me.

The patient cured had the following status:

Aged thirty-five years, married ten years; never pregnant; husband a traveling salesman; menstruation profuse but regular; dysmenorrhea on the first two days, but not so severe but that she could be about. She was very anemic, irritable, and altogether presented the picture of those deplorable conditions so well known to the specialist. Examination showed excessive tenderness, but no change in size or position of the ovaries, and there was also present a moderate endometritis, the pelvic organs being otherwise normal. Of the external genitals, the hypertrophy of the clitoris was very marked. Excision of this and general treatment as to diet and exercise, together with cold douches over the spine and solution of bromide of gold and arsenic, sufficed to cure the woman in a short time.

Abortions, owing to a disregard for proper hygiene and lack of medical care, may exert a detrimental physical effect, which secondarily affects the nervous system. The partial descensus of a large uterus, exerting traction on all the structures aiding to keep it in physiological position, produces disturbances in the circulatory and nerve supply; as the result of this stasis and a probably existing endometritis, menorrhagia occurs, which may be so severe as to cause anemia.

Pelvic inflammations exert a pressure upon the nerves, and likewise cause circulatory changes. These mechanical lesions and alterations extend their influence to neighboring ganglia, the reflex extending to the central nervous system. Some reflex neuroses can also be explained from an aetiological standpoint by the exposure of peripheral nerve terminations from existing erosions and ulcerations of the genitals. Gross anatomical lesions, such as tumors and large exudates, are not apt to cause as much reflex disturbance as the minor lesions mentioned. Displacements of the uterus may cause most intense reflex neuroses. I recollect a case of retroversion, reported by me in the *Deutsche med. Presse*, of New York, in which melancholia with a suicidal tendency was present, a cure being effected by correction of the malposition. The neuroses under the control of the vagus—namely, the heart and respiratory neuroses—have been recognized by several writers in connection with pelvic disease.

In the August number of the *American Journal of Obstetrics* for 1886 I called attention to cardiac neuroses in connection with ovarian and uterine disease. I only wish to add now that during the twelve years which have elapsed the views expressed in that article have not been materially modified; in fact, they have been strengthened by corroborative communication from other observers. When we remember the clinical fact that habitual vomiting, tachycardia, headache, cardialgia, etc., sometimes disappear by curing an inflamed cervix uteri, dilatation of an unusually narrow cervical canal, the correction of a uterine displacement, or the

cure of a diseased endometrium, we can not deny the direct connection between the neurosis and the lesion. At the same time, however, both existing independently, the one may influence the severity of the other.

In our continued investigation of reflex neuroses, let me call your attention to one of the rarer forms, that in which, previous to the occurrence of an attack of hysterical convulsions, vomiting, or crying, the patient feels a painful sensation in the pelvis, back, or abdomen, which seems to radiate upward. Occasionally we can produce an attack by pressure upon a prolapsed and enlarged ovary or some old perimetritic or parametritic residue.

The auditory and optic derangements of nervous and hysterical patients are well known, and it is not at all unusual to have such cases sent by the respective specialists to the gynecologist to find that the primary cause is some disorder of the sexual organs. Among the vasomotor disturbances we can also class hemiparesis and that form of goitre appearing during pregnancy.

The nervous disturbances consisting of mental depression, spinal irritation, and migraine, coexisting with chronic inflammation of the ovaries, are worthy of special attention. One cause for ovarian inflammation and the neuroses dependent upon it may be found in interrupted coition practised by many who do not wish children; it acts the same as masturbation, and is, in my opinion, fully as detrimental.

In the majority of neurasthenic gynecological patients the digestive tract suffers more or less, and the usual dyspeptic treatment will not be of benefit to such women until special measures are undertaken to eradicate the base of the complaint. A differential diagnostic sign between the gastric neurasthenia dependent upon pelvic derangement and the so-called nervous dyspepsia is given by Burkhart, of Germany; it is that in the latter there is pain radiating over the entire abdomen, even over the chest, extending up to the neck and head, when pressure is made over the epigastrium, which is not the case in pelvic gastric neurasthenia.

We have alluded to the difficulty of treatment of the conditions under consideration, and it will be impossible in a paper such as this to give more than a general outline. I must premise the remarks which I shall make on therapeutics with the statement that it is impossible for any one to do more than to come to a problematical conclusion that a reflexive functional neurosis is due to a coexisting pathological lesion of the genital tract. The correct solution of the question must be left to the result of the special treatment. All psychoses with serious symptoms should be under the direction of the neurologist. On the other hand, however, the greater number of functional neuroses can and should be treated by the intelligent family physician, who is familiar with those conditions to which, according to the remarks on this occasion, they are connected. It is a serious error to give a large number of the most general treatment to neurotic patients, and to neglect the local

They will invariably become worse if attention is not paid to general hygiene, diet, proper physical exercise, and such internal remedies as will have a tendency to build up the system. To overcome the anæmia so often associated in this class of cases, I have found the solution of bromide of gold and arsenic to be among the most serviceable drugs at our disposal; beginning with five-drop doses in a glass of water after meals, and increasing one drop daily until from fifteen to twenty drops are taken. The red blood-corpuscles and the percentage of hæmoglobin are rapidly increased with the use of this drug. Occasionally, however, we do find a patient with whom it disagrees, when we must resort to other remedies. The gold solution has also a decided effect on the inflammatory conditions of ovaries. This was pointed out by an author in a European journal ten or twelve years ago, and has been employed during that period by me. Since the introduction of Dr. Barclay's solution, which is a combination with arsenic, it has been used with better effect than the chloride of gold and sodium in pill form. Barclay gave the name arsenaurol to his solution for the sake of brevity. A symptom usually present in these patients is chronic constipation; this often gives rise to anæmia and chlorosis, due to auto-intoxication from ptomaines. I regard the cause of this constipation in the vast majority of cases as due to habit, and if one confines himself to the legion of laxatives and cathartics the condition is made worse.

Correction of diet and habit, together with proper exercise and massage, has usually given the desired effect. Unfortunately, however, abdominal massage is generally improperly applied; it has, therefore, been my rule to give the instruction as to its application personally. The massage must necessarily vary according to the case, and it is therefore obvious why physicians, who simply prescribe massage and leave the method of application to the discretion of the masseuse, do not have such effect follow the treatment as they expect.

The functional neuroses of the menopause, consisting of attacks of vertigo, hot flushes, tachycardia, a feeling of restlessness, and insomnia, have been beneficially influenced by the bromides in large doses, given an hour or two before the time when the symptoms would be most intense, if such intermissions existed, as is occasionally the case. If no regularity can be ascertained, 2.0 of bromide of potassium combined with 0.6 of sulphonal, given in a glass of hot sweetened water at bedtime, is usually sufficient to relieve the symptoms. Some patients, however, do not bear sulphonal, it producing in them a heavy feeling and drowsiness on the following day, without refreshing slumber the foregoing night; in these cases the bromide of potassium, given in doses of 1.3 two to three times daily, has been found serviceable. In neuroses presenting similar symptoms but following ablation of the annexa or removal of the uterus, with or without the ovaries, ovarine has given more relief than the bromide, but the latter are of de-

cided benefit as an adjunct if the attacks of vertigo or hot flushes manifest themselves, particularly at a certain time of the day, as has been frequently observed. In this instance, one single large dose is administered about two or three hours before such time. Blisters behind the ears, alternated with one in the nape of the neck, and the use of the Paquelin cautery at white heat in the latter situation, have been found beneficial in some cases.

The symptoms in neither case, whether due to the natural menopause or to artificial menopause, have been completely allayed, but the condition of the patient, which before treatment is in some instances almost unbearable, usually becomes quite comfortable. In the treatment of all forms of neuroses it is necessary to pay strict attention to diet, giving preference to such foods as contain phosphorus, iron, and fat, unless there is some particular contraindication. In many instances glyco-phosphate of lime, iron in the form of manganese peptonate, or the peptomanganate, blood and iron preparations, such as hæmaboloids, ferratin, bovine, etc., are of advantage.

An important adjunct for the betterment of functional neuroses will be found in hydrotherapy, judiciously employed.

I have found that patients afflicted with functional neuroses are greatly benefited by occupation suitable to their physical development, especially physical exercise.

At no time, however, must we lose sight of the gynecological disorder, which is presumably productive of the respective neurosis.

Let us now consider surgical interference in our cases. This of all forms of treatment is one of the most important. It should never be employed except under the most positive indications, especially in patients with a marked hereditary taint. Where is the physician who has not seen the most lamentable results from the over-assiduousness of the operator who is possessed with operating fever?

I refer particularly to castration for neuroses. But a very small percentage of women who have been operated upon were benefited, and those were in the hands of men who drew the line of indication with the utmost conscientiousness. There are neuroses, especially hysterio-epilepsy, which are not only greatly improved, but absolutely cured by operation. In the cases which have occurred in my own practice there was a decided change from the normal structure of the ovary, and such has been the almost invariable experience of gentlemen universally recognized as painstaking observers. To operate for the cure of hysterio-epilepsy or any other form of functional neurosis, unless we are able to recognize some definite pathological lesion as probably having a connection with the neurosis, is an unjustifiable procedure. On the other hand, it has been my good fortune to relieve three instances of migraine with ovarian neuralgia by resecting that part of the ovary which

had undergone decided cystic degeneration, the diseased structure producing pressure upon the ovarian stroma.

It might be argued that the simple impression of the operation upon the mind cured these patients; against this, however, stands the fact that the three patients referred to have not had a return of the pain, and that there was actually a pathological condition present which would account for the localized pain. The migraine was not associated in my mind at the time with the ovarian change, but its disappearance after operation is sufficient reason to view it as a reflex symptom in these instances.

I may also add that in some patients who are operated upon without immediate beneficial effect on the existing psychosis, the improvement may take place gradually, so that in from six months to three years a complete cure is established. I must reiterate, however, that the operation of oophorectomy for the relief of an intense disturbance of the nervous system is a very serious matter, and should never be undertaken without the utmost scrutiny of all associated conditions; I make bold to say that more harm than good has resulted from it.

A similar statement I would make on other operations, especially euretting, trachelorrhaphy, and perineorrhaphy, which operations have very often been unnecessarily performed.

In closing, I wish to say that I am aware that the theme chosen has been dealt with by me incompletely, my desire being to bring about an interchange of ideas. The result of practical observation shows that the specialist must be qualified in general medicine and not alone in his specialty, and be a physician in the true sense of the word, if his object to relieve the afflicted is to be attained. There are other matters besides pelvic organs and nerves to be looked after in the management of these complex conditions.

THE TREATMENT OF TYPHOID FEVER.*

By WILLIAM L. STOWELL, M.D.

CLINICAL INSTRUCTOR AT THE UNIVERSITY
AND RELIEF HOSPITAL, MEDICAL COLLEGE;
ATTENDING PHYSICIAN TO RANDALL'S ISLAND HOSPITAL, ETC.

Dr. Haughts, the physician to King William and Queen Mary, "was in great Repute with many Families of the greatest Quality and Wealth in the Kingdom." Here is an account in part of his treatment in 1689 of a young lord five years old: "After some Bulimance, because his natural Strength seemed already much weakened by the Disease, I was at last obliged to take at least six Ounces of Blood from his Arm; and the next Day to give a Purge. After the Operation was over a corroborating Julep, chiefly designed to drive away the remains of the Cough, was of sufficient Service to him in his weak Condition that he daily

approached nearer to the most perfect Health, and recovered a good Constitution, which he still enjoys."

In 1890 more than twenty-seven thousand persons died in the United States from enteric fever. That is, in round numbers, the size of our army. For a decade to 1896, this army averaged 138.5 cases of typhoid fever annually with a mortality of nineteen per cent. (Osler).

The borough of Manhattan gives up four hundred lives from this cause yearly.

During the first year of our civil war eight per cent. of the troops had typhoid, and from thirty-five to fifty-five per cent. of them died. The fifty-five per cent. mortality was among the blacks.

In the Spanish-American war just closed about ten per cent. of the troops from New York State had the fever. More complete figures are not at hand.

These facts are sufficient apology for again presenting so old a subject.

As has been well said, "the days of stellar pathology" are gone by. We no longer ascribe the disease to telluric influences, but to a specific germ which has been isolated and cultivated. In addition to the familiar symptoms of typhoid, we can verify our diagnosis in ninety-five per cent. of the cases by Widal's serum test.

Knowing the cause and symptoms, we should be able not only to relieve and cure our patients, but prevent others from being sick.

When we first suspect typhoid we should at once begin the hygienic management. Put the patient to bed in a light, well-ventilated room, etc.

Next begins the management of the patient, for whose comfort we can do much, but with whose disease we can do little. By general consent cases can not be aborted, though we may by skillful care shorten the disease and hasten convalescence. In 1850 West said, "The great object is to carry the patient through an affection which we can not cut short, with as small an amount of suffering and danger as possible." We are in the same position to-day.

The dietetic management is first in importance, and medicinal treatment secondary.

During the first week the digestive fluids are weakened and the appetite is lessened. Light diet should be given, and that in part either which is easily digested and assimilated. Solid or fluid is not the necessary point, but digestibility. Milk is fluid, but is coagulated into a large, firm coagulum in the stomach. If there is little or no further digestion, a solid foreign body exists to irritate, ferment, and cause weight, pain, and tympanites. Sir William Jenner pointed this out long ago. Nevertheless, milk is the best started diet on the beginning. A pint of milk has considerable nutritive value as a good second nutrition food. A young child for maintenance thirty ounces of the milk, and for convalescence three times as much albumin and fat, and for adults three to four carbolons. Nothing so complete a nutritive food to replace meats as milk. The fat and protein of milk are not

* Read before the Society of the Alumni of the City of Health Hospital, November 9, 1898.

use particularly rich milk, as an excess of fat will cause butyric-acid fermentation.

If there is a sense of weight and a feeling that the milk is not readily leaving the stomach, dilute with one third part of lime-water, Vichy, or Seltzer. As the disease progresses and the digestive powers diminish, peptonize the milk partially or completely. Vary the dietary with matzoon or kunyss.

Fresh eggs may be beaten thoroughly and given in milk during the early and latter parts of the disease.

Peptonized milk jelly is relished during the same time. It is simply gelatin added to hot peptonized milk with added sugar and flavoring. Dr. Henry has called our attention to the fact that gelatin saves the consumption of albumin in the system and should be restored to a prominent place in the dietary of the sick. Iced tea, iced cocoa or coffee, and lemonade are all relished. Coffee helps a weak heart.

Wine whey and beef tea are refreshing beverages. The latter, to become nutritive, should have an egg stirred in to supply the deficient albumin.

All the meat juices and broths are wholesome to some degree, but incline to cause diarrhœa, hence must be withheld during the diarrhœa period.

Liquid peptonoids, alone or with Vichy, will prove food and drink for many days. Fruits can be given with care. As the patient becomes apathetic with increasing fever the sense of hunger and thirst is dulled. He must be urged to take food and also to drink. The high temperature uses up the water of which our tissues are more than two thirds composed; hence supply the loss.

As one writer expresses the matter, it is a question whether tissue degeneration is as much due to pyrexia as to drought. Certainly patients feel better and do better when they are liberally supplied with water and urged to take it. Children in particular will drink large quantities. If given in small glasses so that they drain the cup, the satisfaction is doubled. Give more water, sterilized of course, and give it constantly.

Ellis says, "To preserve the powers of the stomach is the keynote of success in the treatment of typhoid fever." Remember also that a single error of diet during convalescence may be fatal.

Medicinal Treatment.—As already stated, the disease will run a course more or less classical in spite of treatment. Nevertheless, many troublesome symptoms can be mollified and unfavorable complications avoided by simple drugs. Of prime importance is intestinal disinfection. To be sure, the damage to the system is caused by toxins produced in the intestinal glands after the bacilli are absorbed. That is no reason why we should not give drugs to destroy any in the intestines still unabsorbed. Calomel is given for this purpose and also to drive forth all invaders. One or two doses given early will be on the severity of many cases. If constipation exist through the first week or longer, Hunyadi water or

citrate of magnesium will benefit. The eliminating action of calomel is its most important effect.

Turpentine and terebene have had extensive trials and proved good, but have now given place to more certain coal-tar products. Naphthalin is said to be the most inimical to typhoid germs. I find salol more agreeable and generally efficient. It breaks up in the intestine into carbolic acid and salicylic acid. These are said to be soluble and so injurious. I have seen no ill effects, though salol comes as near being my routine prescription as any one drug. Thyndol, given in capsules, acts in the same way, destroying the ptomaines of the intestinal alkaloids.

Alcohol is no longer given *ad libitum* and in all cases. Nearly all writers say, Choose the cases, or give alcohol only in the later stages, when the heart is weak, as shown by failing first sound and marked dirotism of the pulse. Subsultus and extreme nervousness are relieved by wine or milk punch. The restlessness of children with typhoid is increased by spirits. They do better under increased nourishment—peptonoids, for example, and a Dover's powder.

The flagging heart and soft, compressible pulse become a source of anxiety during the third week. Camphor, ammonia, strychnine, digitalis, and caffeine are the best heart tonics.

Diarrhœa, if exhausting, is checked by bismuth subgallate, Dover's powder, opium, enemata of starch and opium, or pills of silver nitrate. Dr. Pepper reported one hundred cases treated by the silver method with no death, yet the treatment has not become popular.

Tympanites is often very troublesome. A high injection of normal salt solution will sometimes bring away curds of milk and so relieve. It was Sir William Jenner, I think, who recommended washing the bowel with thin gruel for the relief of the tension and consequent restlessness. Meat preparations instead of milk for a day or two tend to relieve the pressure of gas.

If essence of pepsin and hydrochloric acid have been given freely from the beginning, flatulence will be very uncommon. During my last hospital service there were a dozen patients with the disease, only one of whom suffered from tympanites. Peptonized milk and water exclusively for drink and turpentine stupes outside relieved them in a short time.

Antipyretics are just now boycotted, and justly so. Acetanilide and antipyrine are the most powerful and will soonest reduce a high temperature; but they diminish the elimination of urea and so interfere with metabolism. Their continued use is dangerous and may prolong convalescence by leaving the blood-vessels very weak. At times one or two doses are of the greatest benefit, as in the case of a girl, eighteen years old, whose temperature remained 105°, and who had a dry, beefy tongue with delirium, etc., all of which would not succumb to cold sponging. Two doses of acetanilide reduced the temperature, lessened the nervous disturbance, and brought about a moist state of the tongue.

A similar case I reported to you five years ago, that of a lad who was wildly delirious and made more so by the usual hypnotics. After a full dose of pilocarpine he broke into perspiration, the temperature fell, and the delirium ceased.

Both of these cases emphasize the remark of Henoch that "the uncompromising adherence to a certain method will not always lead to the benefit of the patient."

Quinine was once the favorite antipyretic, but it is less used than it was fifteen years ago. In some instances I find small doses, two or three grains given in capsules with the same amount of phenacetine, will control fever and delirium.

In 1797 Currie advocated the free use of cold water. Hydrotherapy is the most important remedy in the minds of most practitioners at this time. Brand, in 1861, said we had nothing to fear from fever. In 1874 228 cases were treated in Lyons by cold tub baths with a mortality of 10.9 per cent. At the same time and place 290 were treated without baths with a mortality of ten per cent., but they were said to be milder cases. In 1887 Brand cited 1,223 cases with 12 deaths, a fatality of one per cent. Hospital mortality under expectant treatment ranged from fifteen to twenty-five per cent. For instance, Delafield reported 1,305 cases in New York Hospital in 1878-'83 with a mortality of 246, or six per cent. Tuttle reported 76 cases in the same hospital during 1893 under tubbing, with a mortality of five per cent.

Notwithstanding favorable figures running into the thousands, cold bathing or tubbing is not so universal in this country as in Germany. Cold sponging and douching seem sufficient to many men here. The Brand treatment requires the patient to be kept in a cold bath for fifteen minutes every hour if the temperature is above 102.5°. As this causes the extremities to become blue and the teeth to chatter, friction must be kept up until the patient is returned to bed. Stimulants are needed also.

Baruch calls attention to the fact that the circulation is good after the bath, but poor after antipyretics. Antipyretics inhibit cell activity while bathing increases it.

I like sponging with cold water better than tubbing, and with such treatment, conjoined with intestinal antiseptics, have had a mortality of three and a half per cent. in 70 cases. Hemorrhage and perforation are the only complications that contraindicate cold baths. External cold is good treatment for the former. For the latter there was formerly no hope, but Osler says that no case of perforation is too hopeless for a good surgeon. Koch has collected 84 cases operated on with a mortality of nineteen per cent. One in five is worth saving, particularly if one of us happened to be the one.

We come now to what I believe the most important part of the subject—viz., prophylaxis. It is an old

maxim that prevention is better than cure. Use every precaution possible to confine the disease to the one case you are treating. Let the doctor and nurse use freely solutions of bichloride of mercury (1 to 1,000) to which permanganate of potassium is added. Wash hands, thermometers, etc., in it. Boil all bed linen or patient's clothing for several hours. Do not use mercury solutions to disinfect typhoid stools, as an albuminous coating is formed on the outside of solid masses, and multitudes of germs fail to be destroyed. Use lime freely, as this penetrates and annihilates bacilli of all kinds.

A stock solution of chlorinated lime should be ordered, eight ounces to a gallon of water. Of this solution an ounce added to a gallon of water is suitable for disinfecting stools and washing soiled linen.

The stock solution of bichloride is bichloride of mercury, four ounces; potassium permanganate, one drachm; soft water, one gallon. Dilute as in the foregoing.

Where sewerage systems are as good as ours, typhoid stools may be emptied into water closets. In the country great care should be taken to use lime very freely and then bury the excreta, always remembering to avoid the possibility of percolation into a well or stream.

Military prophylaxis has been thoroughly discussed during the past summer. Many of our soldiers had typhoid because they persisted in drinking from a spring which was later found to be only a few feet from an old privy vault. This was carelessness on the part of those who drank and became sick.

In 1885 Plymouth, Pennsylvania, had a frightful epidemic of typhoid because during the winter a careless or ignorant family had for weeks thrown typhoid stools on the bank of a stream back of their house. Plymouth's water supply was contaminated.

In Montclair adults and children died of typhoid because a careless milk dealer, and physician possibly, allowed the milk supply to be infected.

Some one somewhere is remiss, or is without proper knowledge, or else does not use what he does possess. It is our business as physicians not only to cure our patient if we can, but repeatedly instruct nurses and members of families in the nature of typhoid fever, and insist on every possible measure to prevent its extension.

28 WEST THIRTY-SIXTH STREET

COPPER ARSENITE AND NUCLEIN SOLUTION FOR TYPHOID FEVER

By JOHN AULDE, M.D.

THE following reports are offered in connection with the article on this subject which appeared in the *New York Medical Journal of January 10, 1898*. They have been furnished to me by Dr. E. W. Johnson, a long and able surgeon, United States Army, and who has been in the second division hospital of the First Army

Corps, located at Camp Poland, Knoxville, Tennessee, and I have his permission to make extracts from his personal letters sent at the time the reports were forwarded.

Under date of October 17, 1898, Dr. Jackson sent me the first two temperature charts, together with the accompanying comments, and wrote as follows:

"The inclosed reports do not, I believe, require any extended explanation. I have a number of other cases (completed cases) which have not yet been transcribed from the records, for the reason that I have not had the time. Since writing you last I have met with several refractory cases, but I have also a few more favorable cases to add to the number. I believe I can honestly testify to the fact that enteric fever has been favorably modified in nearly if not quite all the cases in which it has been used. The refractory cases were all serious cases from the beginning, and had pulmonary or other complications.

"There is absolutely no doubt as to the specific character of nearly all the cases of fever here. Some of them are, of course, of a mild type, but there are plenty of severe ones. You must understand that I have not felt at liberty to employ this treatment in every case, for the reason that it seemed desirable to make this study with as little ostentation as possible, even though I had the permission of my superior officer, and also the authority from the surgeon-general's office (through the documents sent by you), to test the treatment. A dozen cases carefully observed will be better, it seems to me, than a hundred without proper attention to details.

"To eliminate the possibility of these cases being considered malarial, specimens of blood were examined before quinine was administered. After this, quinine in solution was given to the point of cinchonism, without effect upon the temperature curve or the character of the fever. Dr. George Dock, of Ann Arbor, Michigan, spent several days here, examined many blood specimens for the malarial plasmodium, and announced as his opinion that all continued fever cases in this hospital were cases of true typhoid fever, and this view is held by nearly every member of the medical staff of the hospital.

"I believe the accompanying charts show that the copper arsenite and nuclein solution *did* have a pronounced effect upon the duration of the fever, and I am also prepared to assert that the character of the fever was changed by the administration of these remedies. The chart do not show the improvement in strength, increased comfort, and rapid cleansing of the tongue which occurred in every case. The treatment was instituted rather late in both these cases, owing to the fact that

they were well advanced when supplies and instructions were received. Side by side with these cases there were treated others with the same fever, according to the best and most recent plans in vogue, and it was observed by the nurses as well as myself that the nuclein treated cases made the best progress and did better in all respects.

"I have now under observation a number of men in whom the treatment was instituted earlier than in the cases here given, and the indications are that they will be of rather brief duration and mild, although they were originally severe in type. I am now administering the solution hypodermically, and find that the effects are increased by a slightly heavier dosage than recommended.

"CASE I.—C. S., admitted to the hospital September 15, 1898.

"*History.*—Camped in Chickamunga Park all summer, and came to Camp Poland with troops about the last week in August. Had malaise for some days preceding fever, and diarrhoea; pain in the back, limbs, and head; tongue heavily furred. No chills, or history of chills or sweats.

CASE I.

Clinical Memoranda.—On entrance the patient was given quinine in solution to cinchonism, and calomel, one grain, for three doses.

September 15th patient had guaiacol carbonate, four grains, and salol, five grains, alternately every four hours. A liquid diet was insisted upon.

September 25th patient had nuclein, one minim every hour, copper arsenite, grain one one-hundredth, every three hours, the normal being reached after four days' treatment.

Blood examination for plasmodium malarie negative upon repeated observations. Later, the patient developed iliac tenderness with tympany and apathy, but no vomiting. Rose-spots appeared twice during the course of the fever.

"*Treatment.*—Quinine in solution to cinchonism, with calomel, one grain, for three doses. This was followed by capsules of guaiacol carbonate, four grains, and salol, five grains, alternately, at intervals of four hours. Sponging for temperature above 102.5° F. An occasional dose of cocaine sulphate was given when indicated by sleeplessness or pain.

"Upon September 25th the above treatment was discontinued, and the patient was given nuclein solution, one minim every hour, and copper arsenite, one one-

the temperature touched normal, when tonic treatment consisting of strychnine and 'pil. ferri comp.' (iron, arsenic, and strychnine) was substituted. (See chart.)

"Liquid diet was enjoined."

CASE III.

Clinical Memoranda.—On admission patient had quinine, fifteen grains.

October 2d patient had nuclein solution, ten minims, and copper arsenite, one one-hundredth grain, every three hours. This treatment was continued.

On October 4th, 5th, and 6th patient had profuse perspiration.

This man had been sick in quarters for a period of four days, so that treatment really began on the fifth day of the illness.

The chart shows that the specific infection characteristic of typhoid was arrested after treatment had been continued for a period of two days and a half—when

condition of the muscular system and failure in elimination, but without specific infection.

"CASE IV.—E. H., admitted to the hospital October 1st, and was, to all appearances, a clear case of typhoid fever.

"History.—In Camp at Chickamauga Park during the summer; came to Camp Poland, Knoxville, Tennessee, with other troops about the last week in August. Sick in quarters several days before admission to the hospital. The probable source of infection: infected food or drink in camp or at Knoxville. Patient complained of severe pain in back and head, with nose bleeding. An examination of the blood did not reveal the plasmodium malarie. Patient complained of abdominal tenderness. There were rose-spots present, a typical typhoid-fever tongue and moderate tympany. Diarrhoea was rather severe.

"Treatment.—The accompanying chart shows the course of medication pursued, with its effect upon the temperature curve. A marked abatement in severity of symptoms was consonant with improvement in temperature. The improvement was very marked in this case.

"On October 19th a sudden rise in temperature is noted, which probably bore no relation to the original fever, as it occurred during a sudden cold wave, which made the unheated ward very chilly."

Referring to the accompanying chart, it will be noticed that the temperature approached the normal after treatment had been continued for a period of three days; then followed notable variations for the next two days, after which it was somewhat erratic, but no one familiar with the peculiarities of the disease would insist that it

was a genuine case of typhoid subsequent to the three days of treatment with the two remedies mentioned. Although I have no personal knowledge of the cases under observation further than is shown by these records, I am of opinion that this and several of the others might have been advanced more expeditiously by the conjoint employment of one or more of the following remedies—namely, mercury binioidide, belladonna, or hyoscyamus, according to the special indications present, although I do not deem it expedient to enter upon a discussion of the question at this time.

CASE IV.

Clinical Memoranda.—On admission patient had aloin tablet at six o'clock p. m.

October 2th patient had quinine in solution, five grains to the drachm, every three hours, cinchonism being produced on the afternoon of the 5th.

October 8th patient had nuclein solution, ten minims, and copper arsenite, one one-hundredth grain, every three hours.

October 14th tonics were administered, strychnine arsenite, one thirty-second of a grain, four times a day.

October 19th patient had phenacetin, five grains, two doses.

the temperature fell to 99° F. We have here an apt illustration of the manner in which the nervous system may be affected—shown by the marked variations of the mercury from morning to night, together with the subsequent subnormal temperature, indicating a relaxed

periodicity, the blood was examined for the malarial organism with negative results. During the month of August the patient was slightly jaundiced.

"Treatment.—Quinine was administered to the point of cinchonism, after which the copper arsenite, one one-hundredth grain tablets, with nuclein solution,

"CASE V.—W. M., admitted to the hospital October 6th, with a temperature of 103.4° F., and with the evidences of typhoid infection, such as severe headache, pain in the back, diarrhoea, and general prostration.

"History.—On October 10th a distinct crop of rose-spots appeared. Although there were no chills or other evidences of

ten minims, was given every three hours, as indicated by the accompanying chart. The improvement in the patient's general condition was apparent soon after this treatment was instituted, and the normal temperature was reached on the eleventh day after admission. This

days, with headache, backache, abdominal tenderness, moderate diarrhoea, and coated tongue. Bacteriological examination gave Widal reaction (Philadelphia Bureau of Health, October 31, 1898). Microscopical examination of the blood for *Plasmodium malariae*, negative.

Treatment.—Quinine to cinchonism, given in capsules and solution. Calomel, ten grains in three doses—i. e., one dose of five grains and two doses of two grains and a half each. This treatment covered a period of several days. Guaiacol, five grains in capsules, was then given at intervals of three hours until nuclein medication was instituted.

I should add in this connection that in each case, except No. 3, the clinical diagnosis was confirmed by the Widal reaction test, this work having been done, and the reports sent direct from the bacteriological department of the board of health of the city of Philadelphia, through the courtesy of Dr. A. H. Stewart.

In concluding this report I desire to direct special attention to the supposed function of nuclein in combating disease. It is the name given by experimental physiologists to the product of the polynuclear white blood corpuscles, and chief of the so-called "defensive proteoids." Both typhoid fever and malaria are

man was probably ill for several days prior to admission to the hospital."

An examination of the chart shows that treatment by copper arsenite and nuclein was continued for six full days before the temperature fell to 99°

F., but in view of the history of jaundice, it is not unreasonable to infer that this patient suffered from masked malaria, notwithstanding the failure to discover the plasmodium. Instead of being interpreted as a failure in the treatment, therefore, it should be regarded as another evidence in its favor; since it has been repeatedly demonstrated by clinicians throughout the country that nuclein is our most effective remedy against this particular type of malarial infection. In our Northern climates its success is phenomenal, cases of long standing being arrested within a week after the failure of quinine given in doses as high as sixty grains daily. Professor Edwin F. Wilson, of Columbus, Ohio (*Columbus Medical Journal*, January 22, 1895), reported a case of this nature, in which quinine, arsenic, and Warburg's tincture signally failed, although nuclein alone restored the patient to health within a week.

CASE VI.—E. E., admitted to the hospital October 19, 1898.

History.—Previous history, negative. On admission, complained of chilly sensations for three or four

diseases in which there is an absence of leucocytosis, but by the introduction of an artificially prepared nuclein, we supply these corpuscles with the pabulum which enables them to functionate—that is, to act as scavengers.

CASE V.

Clinical Memoranda.—On admission patient had quinine in solution, five grains to the drachm, to cinchonism.

October 8th (p. m.) patient had nuclein solution, ten minims, and copper arsenite, one one-hundredth grain, every three hours.

October 16th tonic treatment was instituted.

CASE VI.

Clinical Memoranda.—On admission patient had quinine in solution, five grains, in two capsules, of two hours, and on the afternoon of the following day warm sponge-bath.

October 1st, quinine and calomel (p. m.). In the afternoon of the same day, five grains, and quinine, five grains, at intervals of two hours, cinchonism to be produced on the third.

October 8th patient had calomel, ten grains, at ten, twelve, two, and five o'clock.

October 2nd rose spots appeared, the patient had a bath, and was given, each, solution, ten minims, and copper arsenite, one one-hundredth grain, every two hours, and on October 16th tonic treatment was adopted.

to destroy or render inert microorganisms and their products, and it is now believed that these corpuscles bear a close relationship to the phagocytes, first brought to our

attention by Professor Metschnikoff. There is a consensus of opinion among unprejudiced observers that phagocytosis and leucocytosis are complementary functions. The physiological basis of medication by copper arsenite is too well known, and the brilliant clinical successes attending its employment too long established to require further elaboration as a factor in the treatment of typhoid fever.

GENERAL DIRECTIONS FOR THE TREATMENT OF TYPHOID FEVER.—The following general directions have been prepared for the guidance of several medical friends and acquaintances who have thought favorably of the plan of treatment recommended and have expressed their determination to test it when opportunity offers:

Medicinal.—Copper arsenite, one one-hundredth of a grain; nuclein solution, one minim.

The above tablet triturates to be given together, one of each, at intervals of three hours, beginning at six o'clock in the morning and continuing until nine o'clock at night. In urgent cases they should be administered at intervals of two hours for the day; and where the stomach is rebellious, or when the anticipated medicinal effect is not observed, the nuclein is to be given hypodermically in doses of five minims (ten drops) once a day, preferably in the morning, the injection being made at some indifferent point under antiseptic precautions.*

Physiology.—The belief is warranted that the copper arsenite exerts an important influence upon the cellular structures and nerve supply of the small intestine, while the nuclein stimulates the leucocytic function.

Mercury Binioidide.—One one-hundredth of a grain.

This mercurial is employed for defective hepatic action, foul condition of the stomach and coated tongue. One tablet is to be given every hour, or every two hours, for the day, the copper salt being discontinued for the time. In the condition described, with constipation, it will be expedient to administer small doses of a saturated solution of magnesia sulphate.

Strychnine Arsenite.—One thirty-second of a grain.

This remedy is employed to combat muscular relaxation, tone up the weak heart, and overcome the general debility, one tablet to be administered every two to four hours. Whisky or champagne may be employed as stimulants when demanded, although this is rarely necessary when the strychnine salt is administered.

The foregoing directions make no mention of the use of codeine or the bromides as hypnotics, of salol or other intestinal anti-septics, nor of antipyretics, since

there is no apparent demand for such after the patient has been under this treatment for a period of twenty-four hours. Small doses of gelsemium (half a minim of the fluid extract every half hour until five doses have been taken) is to be given for the relief of headache or fugitive pains.

Dietetic.—*Nitrogenous food* should be employed as far as possible, such as beef tea made from a good extract, beef juice, and bouillon.

Hot milk, to which has been added limewater, should be administered, and if not well borne by the stomach, it will be necessary to add a small portion of liquid pancreatin or peplogenic powder, peptonization being completed in the stomach. Junket may be given for a change.

The rule should be, liquid food as far as practicable, given hot, and at the same time as medicines are administered—at intervals of two to three hours. Cold water is allowed in moderation.

1513 ARCH STREET.

THE EARLY DIAGNOSIS, PROGNOSIS, AND TREATMENT OF SEPTIC INFECTION OF THE HAND.*

By J. L. ANDREWS, M.D.

"THE Early Diagnosis and Treatment of *Some Septic Infections of the Hand*" would be a more accurate title for this paper, as it is intended to mention only those forms clinically known as cellulitis, felon, etc.; in other words, those in which there is a tendency toward the formation of suppurating foci in some of the structures of the hand, together with more or less constitutional disturbance. That the subject is important is testified to by the considerable number of missing fingers, hands, and forearms, and the many distressing deformities which we see in private and dispensary practice as a result of septic infection. For discussion it is convenient to classify these cases according to the structures primarily affected: First, those involving the subcutaneous tissue and finger pulp; second, the periosteum; third, the joints; fourth, the tendon sheaths.

In the early stages the diagnosis necessarily rests upon the past and present subjective symptoms and the objective signs. The point of infection may be a small punctured, incised, or lacerated wound, or a blister, scratch, or sliver. In other cases the injury is a blunt one, with no appreciable rupture of the skin. Often the history of the above condition is absent and we have no sign of the point of entry of the poison. Pain is regularly one of the earliest symptoms, usually coming on before any appreciable swelling. When only the subcutaneous tissue is involved the pain is not exerting, or even severe, unless the process is going on under

* Dr. Jackson found better results from larger doses, and I think it is quite possible that his judgment is correct, but a microscopical study of the blood still be required to determine just what effect is produced upon the functional activity of the white blood corpuscles before this question can be definitely settled. Later observations confirm Dr. Jackson's practice, the tablet being dissolved and the nuclein solution used instead, at intervals of four to six hours, in ten minim doses.

* Read before the Society of the Alumni of the City (Charity) Hospital, October 12, 1898.

a thick palmar skin. It is enough to keep patients awake at night, however, but often does not keep them from their work. Tenderness is also an early symptom, but is not very acute until suppuration has taken place or is about to occur. Swelling is present and very apparent early in the disease. When the palm is affected, the thick skin shows little elevation, but instead it will be seen on the dorsal surface.

The functions of the member are regularly impaired or lost, and we find it in a state of partial fixation and flexion. These patients may have one or more chills, fever, etc.; but the constitutional symptoms are not marked, and they do not seem very ill. The bowels are apt to be constipated.

How different is the picture when the periosteum is primarily involved! The pain comes on quickly, is violent and throbbing even in the small periostitis of the distal phalanx. The tenderness is exquisite, but the swelling is not very marked; indeed, it is out of all proportion to the other symptoms. The fever is not high, but chills are frequent without much if any sweating.

When a joint is the seat of septic infection we have great local pain and tenderness, especially on the slightest movement of the parts. The functions are entirely lost. In the earliest stage crepitus is plain enough, but as distention of the joint and circumarticular swelling come on this becomes less prominent. Later, if the articular surfaces are eroded and the fluid escapes, the crepitus becomes harsh and grating. Primary infection of tendon sheath gives quite a characteristic train of symptoms. The pain is most severe and extends up the hand and forearm. Swelling is of the deeper tissues and is not great externally. Tenderness is very acute at the particular point of inflammation and less so along the proximal side of the tendon. Deep pressure on the tendon at a distance seems to draw upon the adhesions that have formed around the inflamed area and causes great suffering. The whole hand is incapacitated and the patient looks very ill. The tongue is coated. The stomach will retain little or no food and constipation or diarrhea is nearly always present.

Chills and fever are regularly early and prominent symptoms. If we seek to control the pain with morphine, large and repeated doses are necessary.

Let it not be supposed for a moment that we claim that all cases can be divided in this more or less systematic manner. For instance, many cases of tendon sheath infection are due to extension by continuity from another structure. Likewise the finger is very apt to be infected from a septic paronychia or tendon sheath.

The prognosis depends upon, first, the virulence of the infection; second, a timely reaction in the patient; third, the structure involved; fourth, the method of treatment.

The virulence of the infection varies in different

cases, and in forming a prognosis is intimately connected with the resisting power of the individual.

It is difficult to think of them separately. Vicious, ill-fed, badly nourished people are apt to suffer much with mild infection, and alcoholic, nephritic, and diabetic subjects regularly do badly. Occasionally we see an apparently strong person infected time after time and in a manner that suggests very slight resistance. Where the subcutaneous tissue is alone involved, with proper treatment and in proper season, the prognosis is good.

The tendency of Nature is toward the formation of localized abscess, rupture through the skin, and granulation from the bottom of the cavity.

In septic arthritis, if not involved with periostitis, the chances of saving the member are good, but the joint function will be somewhat impaired and ankylosis may result.

In septic periostitis, where more important structures are not involved, the prognosis is good. However, the special danger of extension should be borne in mind and the prognosis likewise guarded.

Where the sheath of the tendon is involved we may indeed be anxious. The prognosis is *always* grave as regards the function of the part, and occasionally the life of the patient is in danger. Often the inflamed area becomes shut off from the rest of the sheath and the process becomes limited. In other cases, happily rare, no such protective process occurs and the infection spreads along through the palm, under the annular ligament, and thence up the forearm. If the extremity is saved, the deformity will be great and motion much limited, owing to the sloughing and adhesions of the tendons and their sheaths.

Treatment must be pursued along two lines, local and constitutional. The bowels should be unloaded by calomel or a saline, and such supporting and stimulating treatment adopted as the case seems to require. We have many times given tinctura ferri chlor. in ten- or twenty-drop doses every hour or two, and frequently it seemed to do good. There are cases in which the stomach will not bear the iron even when very well diluted.

Whisky or whisky and stimulants are indicated where the poison is having a depressing effect on the heart. We do not know why, but strychnine does seem to answer a better purpose in these cases than any other cardiac stimulant.

Nourishment should be given up to the full exertive power of the patient. In the case of very ill patients and or semiliquid food is indicated, and in the case of patients from two to three times as much.

Local Treatment.—If we have a patient with a variety within twenty-four hours of the onset of the disease, beginning with a moderate inflammation, and with a moderate tenderness, we might well wait for the formation of a carbuncle, and then attempt to cut it out. If the patient recovers it will be a great deal better than the end of that process than if it were to become a py-

improved we should search carefully for the most tender point and make an incision, taking care to avoid the sheath of tendon, joints, and periosteum. When we see the cases later, and all of the symptoms are severe, it would be better to make an incision at once, even though we find no pus. Especially is this the case on the palmar surface. The relief of tension by cutting the thick, tough skin often prevents a large slough or extension to deeper and more important structures. Wash out every incision with peroxide of hydrogen, drain with gauze, and apply a wet antiseptic dressing. For the later dressings we have found the saturated solution of acetate of aluminum as satisfactory as and perhaps more so than any other.

Where a finger joint is involved it should be incised and drained with gauze on either side. Outside of the antiseptic dressing, a splint will keep the parts quiet and add to the comfort of the patient.

Septic inflammation of the sheath of a tendon should be treated promptly with cold steel. The incision should be free and extend *down to the sheath*, but no farther until the field has been carefully inspected and the overlying connective tissue separated with a sharp knife. Then, if the sheath is found to contain fluid, incise it freely. If not, place a gauze drain in contact with it, but not pressing greatly upon it, and fill the external incision lightly with gauze. Watch carefully for an extension on its proximal side of the tendon, and if it occurs treat it as the primary point.

Septic periostitis should be incised as soon as the diagnosis is made. An exudate under that tense membrane will do much damage in a short time, and should be liberated at the earliest possible moment.

A word in conclusion as to a few general rules. Incision should always be ample in length to allow of proper drainage and facility of after-dressing. If too small, much pain will be given each time the drain is introduced.

Incisions should never be made directly over a palmar tendon, but always on one or both sides, and for this reason, that if you unexpectedly find the sheath of the tendon sloughing, or if it slough late in the course of the disease, the tendon itself will have nothing to confine it, and, owing to the position of flexion that the finger always assumes and the spasm of the muscle that is always present, the tendon is lifted up and stretched across the incision like a bowstring. After this occurs, of course it is doomed to slough beyond the proximal end of the incision.

All incisions should be made clear and clean with a sharp knife. No blunt dissection should be done and the parts should be handled as little as possible.

Always immobilize the affected part. If the dressing is not large enough to accomplish this, apply a splint.

And the main thing secured if we hope to do the best work. For small superficial incisions chloride of ethyl is sufficient. Much may be done with a two-per-cent.

solution of cocaine if skillfully distributed by the infiltration method. Schleich's local anæsthesia has been an utter failure in my hands for this class of cases. Do not hesitate to use a general anæsthetic where the work can not be thoroughly and satisfactorily done with local anæsthesia.

1332 LEXINGTON AVENUE.

THE HYPODERMIC INJECTION OF SILVER NITRATE OVER THE COURSE OF THE VAGI IN THE TREATMENT OF PULMONARY CONSUMPTION. *A PRELIMINARY REPORT.*

By THOMAS J. MAYS, A. M., M. D.,
PROFESSOR OF DISEASES OF THE CHEST IN THE PHILADELPHIA POLYCLINIC;
VISITING PHYSICIAN TO
RUSH HOSPITAL FOR CONSUMPTION IN PHILADELPHIA, ETC.

ABOUT twelve years ago it occurred to me that the lung lesions which are found in pulmonary consumption do not represent the primary morbid changes in this disease, and that they are one of a series of superficial manifestations which are fundamentally dependent on a neurotic basis in which the vagi are seriously implicated. Further study has gone far to substantiate the correctness of my original impression, and has led to the conviction that a rational therapeutics of this most formidable affection naturally rests on a nervous pathology. Hence my armamentarium in the treatment of phthisis has for some years consisted principally of nervous stimulants, like strychnine, electricity, phenacetine, etc. More recently I began giving local attention to the vagi in the region of the neck by massaging, kneading, and compressing them through the overlying textures. These measures seemed to be of benefit so far as the cough, expectoration, and oppression in the chest were concerned, but it soon became evident that their influence was not far-reaching enough to be of decided value. About this time I learned of the usefulness of vagus stretching* in severe cough associated with exophthalmic goitre, and also in epilepsy, and thought of testing this operation in the treatment of phthisis, when it appeared to me that probably the subcutaneous introduction of some active although conservative irritant, like nitrate of silver, immediately over the course of the nerves in the neck might furnish the stimulus necessary to arouse them out of their abnormal condition. An effort was made to carry out the idea, and after many trials and failures it was found that from four to seven minims of a two-and-a-half-per-cent. solution of pure silver nitrate (Merck's) answered the purpose best in the greatest number of instances, although several cases required as much as five minims of a five-per-cent. solution to bring about the desired inflammatory reaction. The

TABULAR VIEW OF THE CONDITION OF FORTY PHTHISICAL PATIENTS BEFORE AND AFTER RECEIVING NITRATE-OF-SILVER INJECTIONS, DIVIDED ACCORDING TO STAGES. NO PATIENT TREATED FOR A MONTH OR LESS IS INCLUDED.

Incipient Cases.

No.	Age.	Time under observation.	Weight when first seen.	Loss or gain.	Cough and expectoration.	Physical signs.	Remarks.
1	Years. 38	6 weeks.	Pounds. 145	Neither.	Disappeared.	Very few remained.	Asthmatic phthisis. Lost eight pounds in a month before treatment.
2	26	2½ months.	169	Gained 4 lbs.	Very much improved.	Disappeared.	
3	18	2 months.	117½	Gained 9 lbs.	Very much improved.	Improved.	Rheumatic element in this case.
4	25	5 weeks.	119½	Gained 3 lbs.	Much better.	Improved very much.	Colored patient. It is well known that phthisis in this race responds slowly to treatment.
5	25	4 months.	109	Gained 16 lbs.	Disappeared.	Disappeared.	Hemorrhagic form.
6	27	6 weeks.	119 at time of first injection.	Gained 10 lbs.	Disappeared almost wholly after first injection.	Very much improved.	Lost one pound in three days preceding first injection. After injection gained at once. Weight at start still previous to third injection, then gained three pounds in two days. Patient colored.
7	60	16 weeks.	137 at time of first injection.	Gained 32 lbs.	Very much improved.	Disappeared.	Lost two pounds and a half in four days previous to first injection.

Advanced Cases.

1	23	2 months.	106½	Lost 7 lbs.	Very much better.	Improved.	Extremely erythritic case.
2	18	3 months.	113	Lost 6 lbs.	Improved.	Improved.	Attendance irregular.
3	29	2½ months.	113	Gained 2 lbs.	Improved greatly.	Improved.	Marked family history of phthisis.
4	44	3 months.	149	Lost 4 lb.	Much improved.	Improved.	Two weeks after first injection weight 155½ lbs.
5	24	2½ months.	119	Lost 2 lbs.	Much improved.	Improved.	Hemorrhagic case.
6	30	3 months.	126	Neither.	Almost entirely relieved for some time.	Improved.	His profuse night sweats also ceased after injections.
7	38	4 months.	105	Neither.	Almost entirely gone.	Very few remaining.	Improved very much in general strength.
8	29	1½ months.	125	Lost 2 lbs.	Almost entirely gone.	Much improved.	Asthmatic phthisis.
9	50	2 months.	114½	Lost 7 lbs.	Very much improved.	Much improved.	Although lost in flesh, she is doing very well.
10	52	2 months.	125½	Lost 1 lb.	Very much improved.	Much improved.	At first lost weight, then rapidly regained it.
11	28	2½ months.	133	Gained 7 lbs.	Improved greatly.	Much improved.	From last account, hemoptysis returned.
12	65	2 months.	139½	Lost 1 lb.	Improved greatly.	Much improved.	Doing remarkably well.
13	21	2 months.	134½	Gained 1½ lbs.	Cough subsided after first injection.	Much improved.	Is working.
14	42	3 months.	133	Gained 3½ lbs.	Very much better.	Much improved.	During first month's attendance reached 110 pounds.
15	38	4 months.	96½	Gained 13 lbs.	Entirely gone.	Much improved. Gone except dullness.	Abscess at seat of injection. Is working.
16	41	3 months.	130	Gained 6 lbs.	Entirely gone.	Much improved.	Lost in weight at first, then rapidly increased.
17	69	3 months.	132	Gained 1½ lbs.	Almost entirely relieved after first injection.	Almost gone.	Rapid recovery.
18	42	6 weeks.	137	Gained 16 lbs.	Practically gone. Cough unusually severe.	Much improved.	First six days gained seven pounds; marked gain after each injection.

Far-advanced Cases.

1	23	2 months.	117½	Lost 4 lbs.	Some relief.	Same.	Complicated with laryngeal mucrocoulis.
2	38	5 weeks.	102½	Gained 2 lbs.	Improved.	Improved.	Lost five pounds in two weeks before first injection.
3	25	5 weeks.	108	Lost 2 lbs.	Improved much at first.	Remained about same.	Night sweats, vomiting, and appetite improved at first.
4	41	2 months.	110	Gained 1 lb.	Improved.	Improved at first.	Vomiting, appetite, night sweats, general strength, sleep, expectoration much improved during first four weeks. Is frequently doing better.
5	34	3 months.	118	Loss not known.	Improved much. Lost a little weight.	Improved.	Appetite, weight, strength, night sweats much improved at first. Is better.
6	38	4 months.	111	Lost 9 lbs.	Very much improved.	Improved.	Appetite, strength, and night sweats improved. Is better.
7	36	4 months.	80½	Loss not known.	Improved. Almost recovered. Still a little cough.	Improved.	Improved for six months in every way, though still coughs.
8	43	2 months.	109½	Loss not known.	Very much improved. Had a good cough in periods, but recovered in a month.	Improved much at first.	Improved for eight months in every way. Now has decided improvement. Is working.
9	55	3 months.	106	Gained 4 lbs.	Very much improved.	Same.	General improvement in every way.
10	16	2 months.	105½	Gained 2½ lbs.	Very much improved. Cough still present.	Same.	General improvement in every way.
11	19	2 months.	131	Lost 4 lbs.	Very much improved.	Same.	General improvement in every way.
12	36	2 months.	98	Gained 1½ lbs.	Improved.	Improved.	General improvement in every way.
13	59	2½ months.	95	Gained 1½ lbs.	Improved.	Improved.	General improvement in every way.
14	52	4 months.	103½	Lost 4 lbs.	Very much improved.	Improved.	General improvement in every way.
15	47	2½ months.	117½	Gained 1½ lbs.	Very much improved.	Improved.	General improvement in every way.

point which has been selected for its administration is immediately over, or slightly behind, the pulsating carotid artery in the region of the neck, midway between the angle of the lower jaw and the clavicle. Other points along the artery have also been chosen. In order to avoid puncturing the carotid artery or its neighboring jugular vein it is important to lift the skin between the thumb and the forefinger of the left hand and introduce the needle just under the elevated skin. The silver solution alone produces considerable local pain immediately after its introduction, and in order to avoid this it is very necessary to precede it with an injection of five minims of a two-and-a-half-per-cent. solution of cocaine hydrochloride.

The following plan has thus far been found the most practical for the introduction of these agents: Inject the cocaine solution; detach the syringe from the needle, and let the latter remain in the puncture. Wash out the syringe with water, draw the silver solution into the syringe, attach the latter to the needle, and throw in the required amount.

The local visible effects of the injection show themselves in nodular, sometimes in diffuse swelling, and in redness and pain; but in no instance have these products become extremely pronounced. Small abscesses have occurred about a dozen times, and a slough once, in about three hundred injections, and two of these were produced by using too strong a solution of silver in the early stage of the experiment. Neither the rupture and discharge of the abscesses nor the small slough in the one instance had any detrimental influence on the patient.

The number of injections which are necessary depends upon circumstances. As a rule, it is a good plan to begin by giving one injection on the side of the neck on which the affected lung is situated.* In a week or ten days this is to be repeated, unless the original or previous injection is followed by too much irritation. In urgent cases due to excessive coughing I have repeated the injections in three or four days. As a rule, it seems best to concentrate the injections on the affected side, and to give an occasional one on the opposite side.

During the last five months I have used nitrate-of-silver injections on forty phthisical patients who were treated longer than a month, and who for convenience sake are divided into incipient (seven), advanced (eighteen), and far-advanced (fifteen) cases. The general effects of the injections on some of the symptoms

* On more frequent use it will be found that pressure over the course of the artery in the region of the neck produces more pain on one than on the opposite side in most phthisical patients, and that this hypersensitiveness usually corresponds with the side having the affected lung.

The general cases with beginning phthisis (ten) show coughing, expectoration, etc. Advanced cases (eight) without coughing, but otherwise showing marked expectoration, loss of appetite, etc. Far-advanced cases (seven) with marked coughing, expectoration, etc.

and conditions of these cases are briefly described in the following analysis:

Cough and Expectoration.—When these injections were first undertaken, it was entirely with a view of benefiting the cough and expectoration in this disease, and it was therefore gratifying to find that they fulfilled this expectation. With but few exceptions these symptoms improved in a marked degree, not only in the incipient and advanced cases, but in the great majority of the far-advanced cases. This was so striking that it could not be mistaken. Besides relieving the cough and expectoration, the injections had a good influence on dyspnea and oppression in the chest; and, as several patients expressed it, gave greater freedom in breathing.

Sleep.—It was noticed that many of the patients slept better. This was probably due to the fact that they did less coughing during the night than previously.

Appetite.—This function was improved in most of the patients, and in many to a marked extent. This was, of course, most noticeable in the incipient and advanced cases, although in nine of the far-advanced cases the appetite was remarkably increased.

General Strength.—This was greatly benefited in most of the incipient and advanced cases, and also in a number of the far-advanced ones. This is probably accountable on the score of a betterment in the digestive function.

Physical Signs.—In many of the incipient and in some of the advanced cases there was noticed a rapid improvement in the physical signs. This was so frequently observed that it could hardly have been merely coincidental.

Weight.—As has already been stated, these injections were solely begun for the purpose of alleviating the phthisical cough and expectoration, and it was surprising, therefore, to find that they also exerted a most beneficial effect on the weight. The gain in weight was observed chiefly in the incipient and advanced cases, but was by no means confined to these, as will be seen in the table on page 195. The internal medication in all these cases was as simple and kept as uniform as possible throughout the experiment—a number of the patients receiving nothing but peppermint water.

The chart on page 197 graphically illustrates the immediate effects of the injections on the weight.

It will be seen that in this example, which refers to patient No. 18 in the list of advanced cases, the weight increased ten pounds and a half in seventeen days after the first injection. At this time another injection raised the weight two pounds and a half more in six days, when it came to a standstill. The third injection on the twenty-fifth day raised it a pound higher in three days, when it came to another standstill. The fourth injection on the thirty-third day raised it two pounds more in six days, when the last observation was taken. None of the other patients gained so rapidly as this one did, although No. 6 of the incipient cases gained

seven pounds in twelve days after the first injection, and three pounds in two days after the third injection; yet the direct effects of the injections on the weight and other conditions were just as apparent in most of the cases that did well. This was especially true of Nos. 3 and 7 of the incipient cases, and Nos. 11, 15, 16, and 17 of the advanced cases. Whether these effects are lasting time alone can determine, but the above histories show that they are at least of decided temporary value.

The deduction which may be drawn from this limited experience with the silver-nitrate injections are (1) that their best results are obtained in incipient cases, both in regard to the symptoms and physical signs of phthisis; (2) that in most of the advanced cases of this disease they have a good and, in some instances, an exceptional influence on the symptoms and physical signs; and (3) that in the great majority of the far-advanced cases they ameliorate the cough, expectation, and some other symptoms temporarily, but have little or no influence on the local condition of the lungs.

In conclusion, I believe that there is much reason for expecting that when this method, even in its present undeveloped state, is combined with other good hygienic, dietetic, and medicinal treatment, such as most of our patients did not receive, the practical benefit will be greater than that represented above. And, moreover, this investigation incidentally points out that the silver injections may play an important part in the therapeutics of asthma, chronic bronchitis, and in the prophylaxis

cal stage in the young which is indicated by a poor and capricious appetite, loss in weight and strength, anæmic, etc.; thus verifying the practice of the eminent Dr. Graves, who, more than fifty years ago, advised the employment of setons beneath the clavicle at the age of puberty whenever phthisis was apprehended.

FIVE RARE CASES OF TUBERCULOUS ULCERATION OF THE SOFT PALATE AND ADJOINING SOFT TISSUES. WITH MENTION OF OTHER CASES OF TUBERCULAR ULCERATION OF THE UPPER AIR PASSAGES.

By EDGAR D. SMITH, M. D.,

INSTRUCTOR OF LARYNGOLOGY AND RHINOLOGY IN THE CHICAGO POLYCLINIC.

TUBERCULOUS ulceration of the soft palate and the adjoining soft tissues in man is considered a very rare disease, rarely more than one dozen cases coming under the notice of the most famous throat specialists. Still it has occurred to me that were the general practitioner more familiar with this subject many more cases would be reported than have been, and this disease would be found not so rare as has formerly been supposed.

To this conclusion I am forced by observing the rapid progress of the disease and the difficulty in diagnosis after the coalescence of the small ulcers, which occurs on the second or third day after the "breaking down" of the separate miliary tubercles. After the coalescence of the small ulcers and the formation of the resulting large ulcer it might readily be mistaken for diphtheria. Again, before the rupture of the separate tubercles, it might readily be mistaken for a condition often seen where there are present minute vesicles containing a clear fluid. But a more serious obstacle to successful diagnosis is the failure of the patient to consult a physician until the large ulcer forms.

While putting these cases on record, I hope to make a few timely observations and bring anew this disease before my fellow practitioners, hoping that, in refreshing their memories, some case may be detected that might otherwise go undiagnosed.

It is altogether probable that the greater part of these cases are secondary to a tuberculous infiltration of the lungs, and that the soft palate and its neighboring tissues are infected by the tuberculous excretions from the lungs. A few of them are doubtless primary and follow from tuberculous dust coming in contact with an abraded mucous membrane. It may follow an abrasion from hot drink, catarrhal or follicular inflammation, or correlative to a cold.

Case II was doubtless of the latter sort, in a north-house, where the dust was so perceptible that it irritated

and congested the nasal mucous membrane so much as to close these cavities and induce mouth breathing. This same dust caused an abrasion of the mucous membrane of the affected parts, and a tuberculous infection followed the breathing in of tuberculous dust.

The nasal mucous membrane is not often infected, owing (in part at least) to the fine hairs at the entrance of the nostrils arresting mechanically the tuberculous bacilli. Still this does not fully explain the infrequency of nasal tuberculosis, and we are obliged to fall back on the oft-observed fact that certain parts are endowed by Nature with a resistance to certain microbes—Nature's wise provision for the preservation of the human kind.

When seen early, the affected part presents a congested appearance. This is followed by an unnatural paleness, which distinguishes it from the surrounding mucous surfaces. Following this come small, seedlike, grayish-white nodules, of the size of a small pinhead. In a few days these break down and small ulcers appear, which, in bad cases, are very numerous. On the second or third day (as mentioned before) these coalesce into a grayish-white superficial ulcer. Unless checked in this stage, this increases rapidly at the edges, and the patient rapidly loses strength and flesh, dying from exhaustion in a short time.

The exhaustion is out of all proportion to the extent of the ulcer, and to me is not easily explainable.

These ulcers are very resistant to medication, and I have found but one remedy that gives satisfactory results. This remedy is a mixture of equal parts of lactic acid and glycerin, applied freely to the ulcer. Under a daily application of this mixture such ulcers as can be easily reached and freely stimulated heal kindly. This may not be true of all cases, but it has been true of at least a dozen that I have personally observed.

CASE I.—A married woman, thirty years of age, came to me in April, 1894, suffering from tuberculous infiltration of the lungs. The right lung was diseased throughout its entirety, while the left lung was apparently free from disease, except at its apex.

The extent of the disease caused me to give an unfavorable prognosis, especially as the larynx was congested, and presented the appearance of what Professor Brown, of the Chicago Polyclinic, is pleased to call the "laryngitis of tuberculosis."

Despite the prognosis, the patient gained in weight and strength, and the laryngitis disappeared under stimulating applications of sulphate of copper, five-per-cent. strength.

In May the patient ceased to come to my office for treatment, and I did not see her again until the early part of June, when, after an absence of four weeks, she returned with a small tuberculous ulcer of the larynx. A few applications of equal parts of lactic acid and glycerin caused the ulcer to heal. I then renewed the former astringent application and she again showed improvement.

During this absence she had lost some weight and more strength, which seemed due to the ulcer mentioned.

In July she again ceased to come to my office, having

nearly twenty miles to come, and her husband, an ex-druggist, made the necessary applications.

I protested against this latter absence, explaining that the applications were very difficult to make in a proper manner, but her husband was certain of his ability to make them.

At first he made them quite successfully, but later he neglected the most important part, the drawing out of the tongue, and failed to reach the larynx.

She agreed to come to my office twice a week, but remained away two weeks. When she made her appearance again the soft palate, the anterior and posterior pillars of the fauces, the tonsils, and the corresponding parts of the sides and posterior walls of the pharynx were thickly studded with milium tubercles. Some of these were ruptured, and the others were about to rupture.

She was now thoroughly frightened and put herself under my daily care. The next day each tubercle was replaced by a small ulcer, and the following day they had coalesced, presenting the appearance of a continuous ulcer of a dirty, grayish-white appearance. In a week, under the lactic acid and glycerin, this ulcer had cicatrized, but she had lost so much strength that she died on the ninth day from exhaustion.

I have always thought that starvation was the chief cause of the exhaustion, since swallowing was so painful that she even avoided water. A few hours before death she sought out and took some food, getting out of bed and going through several rooms, in order to secure this. Her throat had so far healed that swallowing was possible.

CASE II.—This patient has recently come under my observation. He is a man about thirty years of age and has suffered from a cough for some weeks. On December 10, 1898, his wife sent for me, thinking he had diphtheria.

On looking at his throat I found the soft palate, the uvula, and a part of the anterior and posterior faucial pillars studded with minute tuberculous ulcers. A few tubercles were unruptured. I recognized the disease at once (once seen, its recognition is easy), and on the following day made the application before named. At this time I told his wife of its nature and its import. On the second day of my attendance the minute ulcers had become a continuous ulcer. The improvement following the application of glycerin and lactic acid was rapid, and on the 14th inst. the ulcer was nearly healed. Since then the improvement has continued, and his throat is now well, December 21, 1898.

An examination of his chest, December 19, 1898, revealed an infiltration of the entire right lung, most marked in the posterior part of the middle lobe. To me this does not present a hopeless case, since the prompt repair of the ulcers in and about the soft palate and uvula shows a recuperative power quite hopeful for the patient, the more so as I have seen several with more advanced cases entirely recover.

CASE III.—A man, thirty-five years of age, consulted me for a "sore throat." On examination I found the throat very much congested and somewhat edematous. On the following day the soft palate, the uvula, and the anterior pillars of the fauces had assumed a pale color (unnaturally so). At this time I did not recognize the disease, but on the following day the parts before mentioned were studded with milium tubercles.

On the first day I ordered two drachms of tincture of chloride of iron combined with six drachms of glycerin, applied to the throat, every two hours, with a brush. This gave no relief and the pain grew more acute.

On the third day I became aware of the nature of the disease and made a local application of a fifty-per-cent. solution of lactic acid in glycerin. This had the desired effect, and the parts became less painful, and the tubercles remained unruptured. Though the patient has not entirely recovered, the tubercles are being absorbed and recovery seems assured.

CASE IV.—This patient came to my office on the fourth day of the progress of the preceding case under my care. The patient, a woman of about thirty, presented the same appearance as the preceding patient—both as to location and result. The tubercles were just forming, and the mucous membrane was still unnaturally pale. She had been suffering from hoarseness and painful deglutition for some weeks. Of late the pain had become more severe and swallowing was almost impossible.

It is too early yet to report the ultimate result, but the tubercles are now fast disappearing and the pain is much less and deglutition quite easy. She promises to make a rapid recovery.

CASE V.—A young man, twenty years of age, came to my office suffering from endocarditis complicating influenza. This readily yielded to treatment, but it was followed a week later by a "sore throat." On making a careful examination, I found the intense redness that accompanied his influenza was replaced by an abnormal paleness, and within this area of paleness were to be seen some small nodules. These seemed to me to be tuberculous, and I gave a placebo, asking him to return on the following day. He returned as requested. The nodules were not numerous, but their tuberculous character was clearly evident. I at once applied lactic acid in an equal quantity of glycerin, and the nodules, which were limited to the soft palate, uvula, and anterior pillars of the fauces, were absorbed without rupture.

It is yet too early to give the ultimate results, but the present improvement gives promise of a speedy recovery.

Of laryngeal tuberculosis I have seen and treated at least one dozen cases; but one of these deserves special mention. This was a case of mixed infection in a young man about twenty-five years of age. He came to my office after being under the care of a competent physician about seven months. His chief reason for consulting me was a syphilitic ulceration of the epiglottis, vocal cords, and neighboring soft tissues. I required, as usual, a pledge of remaining under my care until I should pronounce him well. This he gave readily, but he ceased to consult me as soon as the ulcerative process was entirely relieved. I met him often and urged the necessity for further treatment. He gave promises galore, but stopped with these.

Two years later he again sought my office for "pain in the throat." An examination revealed ulcers over the arytenoid cartilages and involving the posterior portion of the cords. I gave him the iodules and mercury internally and lactic acid and glycerin as a local

application. The ulcerative process checked in a brief period, but he rapidly lost flesh, and died ten days later. The night of his death he was about the house and in good spirits and cheerful, expressing a confidence of his sure recovery.

I had told his friends that death was imminent and might occur during the night, but they left him without an attendant and found him dead in bed the next morning.

This sudden death in mixed laryngeal ulcers I have noticed in several cases, and when it is recognized (mixed laryngeal ulceration) the attending physician should give a guarded prognosis.

I do not claim any originality in the treatment or description of symptoms in the cases under discussion, but I am hopeful that this refreshment of the memory may aid in the recognition of cases that might otherwise go unrecognized.

306 DIVISION STREET.

Therapeutical Notes.

Against Insolation.—The *Riforma medica* for December 16th recommends a teaspoonful of the following mixture every quarter of an hour until the complete disappearance of symptoms:

R Solution of trinitrine (1 to 1,000) 20 drops;
Water 4,500 minims.

M.

When amelioration begins the doses should be progressively diminished. Tepid compresses of arnica may also be applied to the head.

For Smoker's Stomatitis.—The *Riforma medica* for December 16th recommends:

R Salol 15 grains;
Catechu 30 "
Spiritus of peppermint 750 minims.

M.

A teaspoonful in a tumblerful of hot water for a colatory.

The Treatment of Phthisis.—Goldmann (*Riforma medica*, December 23d) recommends:

R Carbamate of guaiacol, }
Sulphilithyolate of } of each 225 grains;
ammonium, }
Pure glycerin 600 minims;
Peppermint water 150 "

M.

Twenty to thirty drops to be taken daily.

For Tetanic Contraction of the Uterus.—*Riforma medica* for January 2d credits the following prescription to Muller:

R Tincture of iodine 15 grains;
Alcohol 30 "

M.

Five drops in half a tumblerful of hot water every half hour.

NEW YORK, SATURDAY, FEBRUARY 11, 1899.

THE PASSING OF THE TRAINED WRITER.

YEARS ago there sprang up in our country, and perhaps in other lands, a feeling of contempt for accuracy of language, to say nothing of its niceties. "I had rather have one man of common sense than all the grammarians that were ever born," or some equivalent declaration, was frequently heard, and, however much the judicious grieved, the masses applauded. What have been the results? Speech has degenerated, and so has the written language. Many of our people say "probably" when they mean only *perhaps*, to the utter consternation of persons who take words at their true meaning. Statutes have been enacted that can not be parsed and are therefore needlessly difficult to interpret. For a long time syntax was practically neglected in the schools, or else they taught the innovations of a pseudo-grammarian who did his best to play havoc with our time-honored idioms and particularly with the tenses of the verbs in subsidiary clauses. What men wrote for publication came to be esteemed rather for its daring disregard of simplicity and directness of statement than for any display of those fundamental beauties of diction. The great public demanded that the account of any exciting achievement should be written by the man who "did the thing," utterly regardless of his ability to write comprehensibly. Consequently our magazines teem with more or less unintelligible articles; but they are exciting or "sensational," and that satisfies the public desire.

All this has been observed with deep regret by a few who appreciate the importance of preserving the purity of the language, and we are happy to be able to say, for the last four or five years there has been gratifying evidence that the schools have at last come to a realizing sense of their remissness. We understand that rhetoric is now taught as it ought to be taught, and the style of writing counts in examination papers. But much irreparable wrong has been done. It has extended to the medical profession, many of whom, while unquestionably masters in medicine and surgery, are quite incapable of writing with the clearness and cogency indispensable to an adequate exposition of their ideas, or else imperil the credence their statements

might otherwise meet with by coupling them with other statements that are manifestly and ludicrously, though quite unintentionally, false. One effect that the practical extinction of literary capability has had has been to impose upon conscientious editors a grievous and utterly unnecessary task, that of correcting errors of expression and expunging nonsensical statements. We think we may truthfully profess to have exercised quite the average degree of carefulness in performing that portion of the task that has fallen upon us, but we are aware that gross errors sometimes escape our vigilance. Like all other journals that have the respect of their readers, this one is not responsible for the views expressed by contributors, but we do charge ourselves with the work of keeping our columns free from statements that are palpably incorrect.

We greatly regret that an article appeared in this journal for December 10th which contains statements that ought not to have eluded our notice. We regret it all the more because the article was made prominent by being accompanied by colored plates themselves bearing the absurd expression *Plasmodium malaria*. As a matter of fact, these blemishes did not escape our notice, for we distinctly remember setting numerous awkward expressions right and expunging statements that we could not allow to go into the journal. However, by some unfortunate accident, the set of proofs that was corrected in the office never reached the printer. We are indebted to our highly esteemed contemporary the *Cleveland Journal of Medicine* for calling attention to some of the article's peculiarities in its January issue and to several correspondents for pointing out other errors.

THE MORTALITY STATISTICS OF HAVANA.

TOWARD the close of December Sanitary Inspector W. F. Brunner, of the Marine-Hospital Service, rendered to Major-General Francis V. Greene, then in command in Havana, a tabulated report of the mortality of the city for the period embraced between the 1st of January and the 22d of December, 1898. By the courtesy of General Greene we have been enabled to examine Dr. Brunner's report. The table shows 19,271 deaths from all causes. The population of Havana is about 200,000, so that the total number of deaths makes a mortality rate of nearly ten per cent. In round numbers, this is five times as high as the rate for the city of New York, and that, too, for a year in which there were fewer than the usual number of deaths from yellow fever. The figures are as follows: Yellow fever, 136; typhoid fever, 1,030; pernicious fever, 529; malarial

fever, 1,373; dysentery, 1,359; enteritis, 3,149; diphtheria, 21; small-pox, 186; beri-beri, 9; glanders, 8; starvation, 215; pneumonia, 317; tuberculosis, 2,819.

The decrease in the number of deaths from yellow fever is accounted for by Dr. Brunner by the fact that during the year 1898 but few Spanish troops were brought to Cuba. Beginning in April, 1896, he says, an epidemic of small-pox swept Havana, and by the close of the year 1897 it had caused nearly 2,500 deaths, almost exclusively among the natives. Practically, he adds, small-pox has now disappeared from Havana, but is still epidemic in several parts of Cuba.

"The enormous death-rate from tuberculosis," says Dr. Brunner, "is a result of bad hygienic surroundings, meaning bad food, bad homes, and bad morals." The great number of deaths from dysentery and enteritis he attributes to a scant and bad food supply. With 215 deaths attributed to starvation alone, the conclusion can hardly be avoided that insufficient and unwholesome food played no inconsiderable part in the mortality from other diseases than dysentery and enteritis. It becomes more and more evident that we have a tremendous duty to perform in Havana in the way of sanitation. It is to be hoped that the government will take the matter in hand promptly and push the work forward with all the speed that may be compatible with thoroughness.

MINOR PARAGRAPHS.

A COMPARISON OF HYDRASTININE AND COTARNINE.

Rousse (*Archives internationales de pharmacodynamie*, iv, 3, 1, and v, 1, 2; *Centralblatt für Gynäkologie*, January 21st) has found hydrastinine hydrochloride, in pill form, very effective in uterine hæmorrhages, phthisical night sweats, hæmoptysis, epilepsy, and nephritis. Its hæmostatic action is particularly shown in all cases of congestive metrorrhagia, in menorrhagia, in hæmorrhage after parturition and abortion, in hæmorrhage consequent upon displacements of the uterus or diseases of the annexa, and in hæmorrhage during pregnancy and labor. In myoma and carcinoma it is of no use. It has no unpleasant effects; it does not upset the stomach even when given in large doses. Cotarnine hydrochloride slows the action of the heart and gives tone to it, so that it is of great value after hæmorrhage. On the other hand, it has a vasomotor action, although it strengthens and accelerates the contractions of the gravid uterus. Hydrastinine is, therefore, easily distinguished from cotarnine by its greater rapidity of action, so that it may be recommended as a tranquilizer in cases of ether and sulphur, the former being more powerful, but more penetrating, and the latter being more available in chronic uterine affection, especially in the earlier stages. Both drugs strengthen the power of the heart, probably in a way on them. Hydrastinine acts on the uterine and intestinal blood vessels, contracting them. The author thinks, therefore, that hydrastinine

dies are useful in hæmorrhage due to uterine atony, but hydrastinine is to be preferred.

A FINAL WORD ON *PER OS* AND "*PER OREM*."

We are glad to be able to announce that our correspondent "*Boston*" accepts our statement that *per os* is right and *per orem* wrong. Indeed, he himself furnishes us with a passage from a classical author—Ovid. He thinks—which, as he remarks, settles the question. The passage is: *Os homini sublime dedit, calumque lueri*.

THE NOUVELLE ICONOGRAPHIE DE LA SALPÊTRIÈRE.

THE issue of this journal for November and December, 1898, may be regarded as a Charcot memorial number. It gives a full account of the inauguration of the statue erected to the memory of that famous physician scientist in Paris, including the orations of Professor Brouardel, Dr. Navarre, Professor Raymond, Professor Cornil, and M. Leygues, Minister of Public Instruction. There is an admirable representation of the Charcot statue as a front-piece, while at the end of the journal is a very interesting account of Charcot as an artist, accompanied by eight plates reproducing his designs, and numerous cuts in facsimile. The writer of the article concludes thus: "And who knows? If by chance in the early family council which decided his destiny, Charcot had preferred art to medicine, is it not possible that even then he would have succeeded in making his name illustrious?"

OIL OF WINTERGREEN IN THE TREATMENT OF CHOREA.

According to Luigi (*Riforma medica; Gazette hebdomadaire de médecine et de chirurgie*, January 8th), Professor Bozzolo, who introduced oil of wintergreen as a remedy for rheumatism, has demonstrated also its antipyretic action in erysipelas and scarlet fever and its antiseptic virtues in urinary and pulmonary diseases. In Bozzolo's clinic it is now looked upon as the most available of the antirheumatic in the treatment of chorea in children. The oil of gaultheria, combined with its own weight of vaseline, is employed locally over painful joints, and not only ameliorates the pain, but also benefits the chorea.

THE GAZETTE MÉDICALE DE PARIS.

THIS well-known journal, now in the seventh year of its publication, is said to be the best French medical periodical. In the issue for January 11th we find the name of Dr. Marie Rodière as the new editor in chief. It is announced that the *Gazette* will be enlarged, that more illustrations will be added, and that other respects the features of the journal will be improved.

ALBUMINURIA AND GLYCOSURIA AFTER HEAD INJURY.

THE following cases were reported by Dr. J. B. Bouchard, of Lyons, in the *Revue médicale*, 1898, No. 10, p. 100. The first case was that of a man, 40 years of age, who had been injured by a fall from a height of 10 meters, and who had been in the hospital for 10 days. The second case was that of a woman, 35 years of age, who had been injured by a fall from a height of 5 meters, and who had been in the hospital for 10 days.

sary to examine the urine immediately after the injury, before the abnormal state of the secretion has time to develop in consequence of the hurt.

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 4, 1899:

DISEASES.	Week ending Jan. 28.		Week ending Feb. 4.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	14	6	12	5
Scarlet fever.....	202	11	229	18
Cerebro-spinal meningitis.....	0	6	0	4
Measles.....	174	13	153	12
Diphtheria.....	197	30	182	40
Croup.....	10	3	14	9
Tuberculosis.....	200	191	198	189
Small-pox.....	0	0	1	0
Chicken-pox.....	27	0	35	0

The Western Ophthalmological, Otological, and Laryngological Association.—The annual meeting was held in New Orleans, on Friday and Saturday, February 10th and 11th, under the presidency of Dr. J. Elliott Colburn, of Chicago. In addition to the president's address, the programme included the following titles: Address of Welcome, by Dr. Charles Chassaignac, of New Orleans; Response, by Dr. B. E. Fryer, of Kansas City; Historical Notes relating to Strabismus and other Anomalies of the Eye Muscles, by Dr. George T. Stevens, of New York; The Treatment of Acute and Chronic Glaucoma, by Dr. Dudley S. Reynolds, of Louisville; Profuse Hemorrhage Subsequent to Extraction of Senile Cataract, by Dr. B. E. Fryer, of Kansas City; Luxation of Both Lenses giving Rise to Glaucoma, by Dr. A. R. Amos, of Des Moines, Iowa; Some Experiences with Dr. Gould's Method of Prismatic Exercises, by Dr. Cassius D. Westcott, of Chicago; The Percentage of Color Blindness to Normal Color Vision as computed from 308,919 Cases, by Dr. J. A. Mullen, of Houston, Texas; Some Experiments with the Giant Magnet, by Dr. Hamilton Stillson, of Seattle, Washington; The Treatment of Diseases of the Lacrymal Duct by Cataphoresis, with an Exhibition of Cupped Sounds, by Dr. C. F. Keiper, of Lafayette, Indiana; Further Observations concerning the Check Ligament, by Dr. J. Elliott Colburn, of Chicago; Glioma of the Medulla, with a Report of Autopsy and Microscopical Examination, by Dr. Casey A. Wood, of Chicago; Spontaneous Hemorrhage of the Nasal Septum, by Dr. Marcel Nattier, of Paris, France; Synopsis of the Functions of the Eustachian Tube, Mastoid Cells, Tensor Tympani, and Stapedius, by Dr. Thomas F. Rumbold, of St. Louis; Vicarious Menstruation through the Intact External Auditory Canal, by Dr. K. K. Wheelock, of Fort Wayne, Indiana; The Diagnosis and Treatment of Incipient Laryngeal Cancer, by Dr. Max Thorne, of Cincinnati, and Dr. W. Scheppegrell, of New Orleans; The Principles of the Therapeutics of Stuttering, by Dr. R. Coen, of Vienna, Austria; The Indication for Middle-ear Operations, by Dr. W. L. Billerbeck, of Chicago; The Offending Middle Turbinate, by Dr. Edwin P. Johnson, of Chicago; The Relation of Trachoma of the Conjunctiva to Diseases of the Nose, by Dr. C. Zaem, of Warsaw, Russia; Collective Investigation as to the Relative Frequency of Adenoids

in Different Parts of the Country, by Dr. E. C. Ellett, of Memphis; The Best Vision after Cataract Extraction, by Dr. W. E. Driver, of Norfolk, Virginia; A Case of Bell's Palsy and Epilepsy cured by Correction of Anisotropia and Heterophoria, by Dr. L. R. Culbertson, of Zanesville, Ohio; Injuries of the Eyeball, with a Report of Cases, by Dr. E. O. Sisson, of Keokuk, Iowa; 1899 Skiascope, by Dr. J. Ellis Jennings, of St. Louis; A Study of Conjunctival Ulceration, by Dr. H. McI. Morton, of Minneapolis; The Congenital Arrest of Development of the Cornea, by Dr. K. K. Wheelock, of Fort Wayne, Indiana; A Report on the Operative Treatment of Myopia, by Dr. H. V. Würdemann, of Milwaukee; The Etiology and Importance of Iritis, by Dr. H. H. Brown, of Chicago; The Pathology of Cataract, by Dr. Adolph Alt, of St. Louis; The Surgery of the Accessory Sinuses of the Nose, by Dr. Augustus McShane, of New Orleans; Empyema of the Accessory Sinuses of the Nose, by Dr. W. W. Bulette, of Pueblo, Colorado; Medication of the Tympanic Cavity, by Dr. M. A. Goldstein, of St. Louis; Agoraphobia in Relation to Diseases of the Ear, by Dr. A. A. Guye, of Amsterdam, Holland; The Importance of the Early Recognition and Treatment of Catarrhal Diseases, by Dr. William Scheppegrell, of New Orleans; Fifty Mastoid Operations, including Four Brain Abscesses and One Perforation of the Sigmoid Sinus, by Dr. D. Milton Greene, of Grand Rapids, Michigan; A Case of Temporal Abscess Drained through the Attic after Ossiculectomy and Curettement, by Dr. Hamilton Stillson, of Seattle, Washington; The Radical Treatment of Fibroid Nasopharyngeal Polypi, by Dr. E. J. Moure, of Bordeaux, France; Refraction of the Trachomatous Eyes, by Dr. E. E. Hamilton, of Wichita, Kansas; Large Tumor of the Brain encroaching on the Motor Area and causing Few Symptoms save Optic Neuritis; with Remarks on Double Neuritis as a Sign of Brain Tumor, by Dr. J. Moores Ball, of St. Louis; Some of the Failures, Immediate and Remote, encountered after Cataract Extraction, by Dr. J. Morrison Ray, of Louisville; Keratitis Herpetica, by Dr. S. S. Ledbetter, of Birmingham, Alabama; Ulcerative Keratitis and how to Cure it, by Dr. R. F. Lemond, of Denver; A Series of Cases of Keratitis, with Reports of Blood Examination, by Dr. E. C. Ellett, of Memphis; Uric Acid as a Factor in the Causation of Chorioiditis, by Dr. Randolph Brunson, of Hot Springs, Arkansas; An Ophthalmologist's Experience with the Army, by Dr. J. J. Kyle, of Marion, Indiana; Persistent Pannus cured as a Result of Acute Daeruoeystitis, by Dr. J. Ellis Jennings, of St. Louis; Indications for Operative Interference in Chronic Suppurative Otitis, by Dr. Norval H. Pierce, of Chicago; Congenital Nasal Atresia, by Dr. Hal Foster, of Kansas City; Laryngeal Disturbances in Diseases of the Nervous System, by Dr. Jonathan Sendziak, of Warsaw, Russia; Tuberculosis of the Tonsils, Pharynx, and Larynx, by Dr. W. T. Grove, of Eureka, Kansas; Tuberculous Fleets of the Pharynx, by Dr. W. L. Dayton, of Lincoln, Nebraska; The Diagnosis and Treatment of Tuberculous Laryngitis, by Dr. George Knapp, of Vincennes, Indiana; and The Diagnostic Importance of Cough, by Dr. Fayette C. Ewing, of St. Louis.

The St. Louis Medical Society.—At the last regular meeting, on Saturday evening, the 4th inst., Dr. I. N. Love read a paper entitled Some Personal Experiences and Observations with *La Grippe*.

The Buffalo Academy of Medicine.—At the last meeting of the Section in Surgery, on Tuesday evening,

the 7th inst., the following papers were presented for discussion: Stricture of the Lacrymal Duct; Treatment by Electrolysis and Otherwise, by Dr. B. H. Grove; and The Treatment of Hernia without Operation, by Dr. William C. Phelps.

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, plague, and cholera were reported to the supervising surgeon-general of the United States Marine-Hospital Service for the week ending February 4, 1899:

Small-pox—United States.

Clarke, Ala.	Jan. 27	Small pox present.
Clay, Ala.	Jan. 27	Small pox present.
Dallas, Ala.	Jan. 27	Small pox present.
Greene, Ala.	Jan. 27	Small pox present.
Hale, Ala.	Jan. 27	Small pox present.
Lowndes, Ala.	Jan. 27	Small pox present.
Marion, Ala.	Jan. 27	Small pox present.
Mobile, Ala.	Jan. 1-27	7 cases.
Randolph, Ala.	Jan. 27	Small pox present.
Palaski County, Ark.	Jan. 27	Several 1 death.
Washington, D. C.	Jan. 14-21	1 case.
Cairo, Ill.	Jan. 27	2 suspicious cases.
Indianapolis, Ind.	Jan. 22	3 cases, origin unknown.
Louisville, Ky.	Jan. 23	1 case on river steamer.
Detroit, Mich.	Jan. 7-11	7 cases.
Clay County, Miss.	Jan. 27	Small pox present.
Jones County, Miss.	Jan. 27	Small pox present.
Hattiesburg, Perry County, Miss.	Jan. 27	17 cases in pest-house.
Lauderdale County, Miss.	Jan. 27	Small pox present.
Noxubee County, Miss.	Jan. 27	Small pox present.
Tishomingo County, Miss.	Jan. 27	Small pox present.
Omaha, Neb.	Jan. 17-22	7 cases.
Jersey City, N. J.	Jan. 15-22	2 "
Dunkirk, N. Y.	Jan. 14-21	2 "
Laredo, Texas.	Jan. 14-21	27 " 8 deaths.
Alexandria, Va.	Jan. 23-29	17 "
Portsmouth, Va.	Jan. 27	16 "
Richmond, Va.	Jan. 25	1 case.

Small-pox—Foreign.

Antwerp, Belgium.	Jan. 1-7	4 cases.
Bombay, India.	Dec. 20-27	2 deaths.
Calcutta, India.	Dec. 10-17	1 death.
Mexico City, Mexico.	Jan. 15-22	1 "
Halifax, N. S.	Jan. 28	1 case among Russian immigrants.
Moscow, Russia.	Dec. 24-31	13 cases.
Moscow, Russia.	Dec. 31-Jan. 7	7 " 1 death.
Odesa, Russia.	Jan. 1-7	1 case.
Constantinople, Turkey.	Jan. 2-9	11 deaths.
Smyrna, Turkey.	Dec. 25-Jan. 1	2 "

Yellow Fever.

Barranquilla, Colombia.	Jan. 2-9	1 case.
Vera Cruz, Mexico.	Jan. 12-19	2 deaths.

Plague.

Hongkong, China.	Dec. 10-17	1 case.
------------------	------------	---------

Cholera.

Bombay, India.	Dec. 20-27	2 deaths.
Calcutta, India.	Dec. 10-17	16 "

An "Osteopathist's" Suit against a Medical Journal.—At the recent meeting of the Medical Society of the State of New York, the following preamble and resolution, introduced by Dr. A. M. Phelps, of New York, were adopted unanimously:

Whereas, We, the regular practitioners of medicine, are opposed to anything which under color of law, or in the operations of charlatans without medical license, and

thists" have received legislative recognition in several States; and

Whereas, A certain William Smith, osteopathist, has been denounced, together with his fellow charlatans, by the *Medical Age*, and now brings suit against both the publisher and editor of the *Medical Age* for damages in the sum of twenty-five thousand dollars:

Therefore, Be it declared the sentiment of the Medical Society of the State of New York that the editor and publisher of the *Medical Age* are entitled to the sympathy of the members of this society and of all medical practitioners: that we wish them success in repelling this legal assault; that we recognize in their action a valuable effort toward the suppression of such irregularities in medicine; and that we recognize that when the *Medical Age* takes such a bold stand in opposition to quackery it promotes the interests of legitimate and honorable medicine and the welfare of humanity.

A New Baltimore Quarterly.—The *Journal of the Alumni Association of the College of Physicians and Surgeons, Baltimore*, is one of the new medical periodicals. It has now reached its fourth number. It is edited by Dr. William S. Gardner.

The Late Dr. Judson C. Smith.—At a meeting of the medical staff of the DeWitt Dispensary, held February 1, 1899, the following resolutions were unanimously adopted:

Whereas, It has pleased Almighty God to remove our late associate, Dr. Judson C. Smith; and

Whereas, As colleagues we had reason to respect his professional attainments and his character as a man and a physician, recalling the friendship which existed in our work in the dispensary; therefore, be it

Resolved, That by the death of Dr. Smith we feel that the medical profession has lost an active, conscientious member;

Resolved, That we extend our profound sympathy to the family of Dr. Smith in the hour of their bereavement;

Resolved, That a copy of these resolutions be sent to the family of the deceased and to the medical press.

[Signed.] JOHN H. FRENCH, M. D.,
WILLIAM B. NOYES, M. D.,
SILAS F. HALLOCK, M. D.

Changes of Address.—Dr. William Richter, to No. 320 Second Avenue; Dr. M. Weiss, to No. 217 East One Hundred and Fourth Street.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 28 to February 1, 1899.*

ACKER, GEORGE W., First Lieutenant and Assistant Surgeon, is honorably discharged from the service of the United States.

APPEL, ARON H., Major and Surgeon, is relieved from temporary duty at Fort Hancock, N. Y., and will proceed to Fort Clark, Tex.

DECKER, OLIVASOR, Major and Brevet Surgeon, will proceed to Havana, Cuba, as acting commanding general, Department of Cuba.

GLISSAN, JAMES T., Major and Brevet Surgeon, is relieved from duty at Fort Hancock, N. Y., and will proceed to Manila, P. I., as acting assistant for duty.

GREENLEAF, CHARLES B., Colonel and Assistant Surgeon-General, will proceed to Savannah, and there take passage on the hospital ship *Bay State* to Cienfuegos, Cuba, stopping at such intermediate places as may be designated by the surgeon-general of the army, for the purpose of inspecting the medical department at those stations. From Cienfuegos Colonel Greenleaf will proceed to such other places in Cuba as may be necessary, to inspect their sanitary condition and to perfect arrangements for the care of the sick.

LEWIS, WILLIAM F., Captain and Assistant Surgeon, is assigned to temporary duty as examiner of recruits in Baltimore.

MARROW, CHARLES E., First Lieutenant and Assistant Surgeon, is relieved from further duty on the hospital ship *Bay State*, now at Savannah, and will proceed to Avila and report to the commanding officer of the battalion of the Fifteenth Infantry at that place for duty.

MAUS, LOUIS M., Lieutenant-Colonel and Chief Surgeon, is relieved from further duty with the Seventh Army Corps, and will proceed to Fort Hamilton, New York, for duty.

ROBERTS, GEORGE W., Captain and Assistant Surgeon, is honorably discharged from the service of the United States.

THOMASON, HENRY D., Major and Brigade Surgeon, is relieved from temporary duty at Fort Clark, Texas, and will proceed to his home and await orders.

WINN, WILLIAM B., Major and Brigade Surgeon, will proceed to Havana for duty.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the Two Weeks ending February 4, 1899:*

ANGENY, G. N., Assistant Surgeon. Detached from the Naval Hospital, Chelsea, Massachusetts, and ordered to the *Indiana*.

ANGENY, G. L., Assistant Surgeon. The order detaching him from the Naval Hospital, Chelsea, Massachusetts, and ordering him to the *Indiana* is revoked.

BALDWIN, L. B., Surgeon. Detached from the naval recruiting rendezvous, New York, and ordered to await orders.

BERTOLETTE, D. N., Surgeon. Detached from the *Vermont* and ordered to duty as a member of the medical examining board, Washington.

BEYLER, H. G., Surgeon. Detached from the *Amphitrite* and ordered to the *Wabash*.

BLOOMGOLD, D., Medical Director, retired. Detached from special duty at New York and ordered home.

BOGERT, E. S., Medical Director, retired. Detached from special duty at New York and ordered home.

BOGERT, E. S., JR., Passed Assistant Surgeon. Ordered to additional duty in attendance on officers of the navy and marine corps at New York.

CLIBORN, C. J., Medical Director. Detached from duty in charge of the Naval Hospital, Norfolk, Va., and ordered to the Naval Hospital, Philadelphia.

COBLE, C. H., Medical Director, retired. Detached from the Naval Hospital, Philadelphia, and ordered home.

CRANE, T. C., Surgeon, retired. Detached from duty as a member of the board of medical examiners, New York, February 1st, and ordered home.

CURTIS, L. W., Surgeon. Ordered to the *Vermont*.

DICKINSON, D., Medical Inspector. Detached from the *Philadelphia* and from duty as fleet surgeon of the Pacific Station.

DUNN, H. A., Assistant Surgeon. Detached from the *Cincinnati*, when put out of commission, and ordered to the Naval Hospital, Chelsea, Massachusetts.

EDGAR, J. M., Surgeon. Detached from the *Cincinnati* and ordered to the *Richmond*.

FEEBEE, N. M., Medical Inspector. Ordered to the Naval Hospital, Norfolk, Virginia.

FIELD, J. G., Assistant Surgeon, retired. Detached from the *Richmond* and ordered home.

FREEMAN, G. F., Assistant Surgeon. Detached from the *Arethusa* and ordered to temporary duty on the *Vermont*.

GARTON, W. H., Assistant Surgeon. The order detaching him from the *Supply* and ordering him to the Washington Navy Yard is revoked.

HARMON, G. E. H., Surgeon. Detached from the *Newark* and ordered to the *Amphitrite*.

HOLCOMB, R. C., Assistant Surgeon. The order detaching him from the Naval Academy and ordering him to the Washington Navy Yard is revoked.

LAW, H. L., Surgeon, retired. Detached from the *Wabash* and ordered home.

McMURTRIE, D., Medical Director, retired. Detached from duty as president of the medical examining board, Washington, and ordered home.

PARKER, EDWARD G., Assistant Surgeon. Appointed January 10, 1899.

PARKER, E. G., Assistant Surgeon. Ordered to the *Pensacola*.

ROSS, J. W., Surgeon, retired. Ordered to report to the War Department for duty in connection with one of the hospitals to be established at Havana, Cuba.

RUSSELL, A. C. H., Surgeon. Detached from the Bureau of Medicine and Surgery and ordered to the *Newark*.

STOKES, C. F., Passed Assistant Surgeon. Ordered to duty as a member of the board of medical examiners, New York.

SNYDER, J. J., Assistant Surgeon. Detached from the *Wabash* and ordered to temporary duty at the Naval Hospital, Newport, Rhode Island.

VON WEDEKIND, L. L., Passed Assistant Surgeon. Detached from the Naval Academy, and ordered to the Asiatic Station via the *Salace*.

Society Meetings for the Coming Week:

MONDAY, February 13th: New York Academy of Medicine (Section in General Surgery); New York Academy of Sciences (Section in Chemistry and Technology); New York Medico-historical Society (private—anniversary); New York Ophthalmological Society (private); Lenox Medical and Surgical Society, New York (private); Harlem Medical Association of the City of New York; Gynecological Society of Boston; Burlington, Vermont, Medical and Surgical Club; Norwalk, Connecticut, Medical Society (private).

TUESDAY, February 14th: New York Academy of Medicine (Section in Genito-urinary Surgery); New York Medical Union (private); New York Obstetrical Society (private); Buffalo Academy of Medicine (Section in Medicine); Kings County, N. Y., Medical Association; Rome, N. Y., Medical Society; Medical Society of the County of Rensselaer, N. Y.; Newark (private) and Trenton, N. J., Medical As-

sociations; Clinical Society of the Elizabeth, N. J., General Hospital and Dispensary; Northwestern Medical Society of Philadelphia; Practitioners' Club, Richmond, Kentucky; Richmond, Virginia, Academy of Medicine and Surgery.

WEDNESDAY, February 15th: Medico-legal Society, New York; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark).

THURSDAY, February 16th: New York Academy of Medicine; Brooklyn Surgical Society; Bedford, Massachusetts, Society for Medical Improvement (private); Medical Society of City Hospital Alumni, of St. Louis; Atlanta Society of Medicine.

FRIDAY, February 17th: New York Academy of Medicine (Section in Orthopedic Surgery); Clinical Society of the New York Post-graduate Medical School and Hospital; Baltimore Clinical Society; Chicago Gynecological Society.

Births, Marriages, and Deaths.

Married.

KANTZ—KEAMER.—In Berryburg, Pennsylvania, on Wednesday, February 1st, Dr. A. J. Kantz and Miss Ella Keamer.

LUTZ—STEPPE.—In Brooklyn, on Wednesday, February 1st, Dr. Stephen Henry Lutz and Miss Winnifred Steppe.

McCord—FARRINGTON.—In New York, on Wednesday, February 1st, Mr. Robert Archibald McCord and Miss Kittie Louise Farrington, daughter of Dr. Joseph O. Farrington.

Died.

CAMPBELL.—In New York, on Sunday, February 5th, Dr. William C. Campbell.

GOODENOUGH.—In Long Branch, N. J., on Wednesday, February 1st, Dr. Joseph B. Goodenough, in the seventy-third year of his age.

HENDERSON.—In Brooklyn, on Monday, February 6th, Dr. Alvin C. Henderson, in the fiftieth year of his age.

JEWETT.—In Grafton, Massachusetts, on Saturday, January 28th, Mrs. Harriet C. Jewett, wife of Dr. Frederic A. Jewett.

KANTZ.—In Berryburg, Pennsylvania, on Thursday, February 2d, Dr. A. J. Kantz, in the sixty-second year of his age.

PARKER.—In Boston, on Tuesday, January 31st, Mrs. Frances M. Parker, wife of Dr. Charles F. Parker.

PEACOCK.—In Jersey City, on Tuesday, February 7th, Dr. Rufus W. Peacock, in the seventy-third year of his age.

ROHÉ.—In New Orleans, on Tuesday, February 7th, Dr. George H. Rohé, of Baltimore, aged forty-eight years.

Obituaries.

GEORGE H. ROHÉ, M.D., OF BALTIMORE

As we go to press, the newspaper dispatches announce the sudden death of Dr. Rohé in New Orleans.

whether he had gone to attend a meeting. He was a well-known alienist and the superintendent of the Maryland State Insane Asylum. He died at the early age of forty-eight years. Dr. Rohé was an excellent writer and a highly respected member of the medical profession.

THE RIGHT TO PRACTISE MEDICINE AND SURGERY.

(Continued from page 172.)

Revocation of License.—The power to revoke as well as to grant licenses is generally conferred upon the examining board. The law conferring this power upon the board has been attacked upon the ground that it is unconstitutional, being a judicial function, and therefore only to be vested in the courts; but such objections have been universally held to be ill founded. The grounds usually designated by the statute upon which the board is empowered to revoke a certificate or license are "unprofessional, dishonorable, and immoral conduct." The careful examination of a few cases of this character will best show what conduct the courts consider as being unprofessional, dishonorable, and immoral.

Advertising.—The word "unprofessional," as used in those statutes, has been judicially defined as being synonymous with dishonorable and not referring to matters of professional ethics,* as it is considered unprofessional from an ethical point of view for a physician to advertise himself or his business; yet, if the advertisements contained no objectionable matter, such advertising would not be ground for revoking his certificate.

If, however, such advertisement contained matter which the physician knew to be false, and it was made for the purpose of deceiving and imposing upon the public, such conduct would be "unprofessional and dishonorable" in the sense contemplated by the statute. For instance, an advertisement which asserted the physician's ability to speedily cure *all* chronic nervous, blood, and skin diseases of both sexes, also *all* diseases of the eye and ear, without injurious drug or hindrance from business; *all* old, lingering constitutional diseases, where the blood is impure, causing ulcers, blotches, sore throat and mouth, pains in the head and bones, *cured for life*, etc., was held to be "unprofessional conduct of the grossest kind."†

Misrepresenting the Character of Disease. The statutes of Ontario provide that a license may be revoked for "infamous or disgraceful conduct in a professional respect." A physician represented to his colleagues in the last stages of consumption that they were suffering from catarrhal bronchitis and that he could cure them, by strength of which representation he secured money from them. The court said: "It was a disgraceful conduct

* See *State v. Wood*, 114 N. W. Rep., 470.

† *State v. State*, 114 N. W. Rep., 470.

disgraceful in the common judgment of mankind, and much more in a professional respect." Moreover, it is a very serious question whether such conduct does not amount to the crime of obtaining money under a false pretense.* This question is discussed under the head of Criminal Liability.

Concealing a Fetus.—A case of considerable interest once arose in Montana, and because of its interest it is discussed at length.

A complaint was filed with the State board of medical examiners for the purpose of revoking the defendant's license for unprofessional, dishonorable, and immoral conduct. The complaint stated in substance that the defendant placed in the furnace a package containing a headless fetus, about seven months old, with intent to destroy the same and conceal its birth; that at the coroner's inquest over the fetus the defendant testified that he had been called to attend a woman who suffered a miscarriage; that while being delivered the head of the infant became detached; that the patient from whom the fetus was taken asked not to have her name made public; he therefore refused to disclose the name, but stated that on the following day he would state the name to the coroner, who would use his discretion in the matter. That on the following day defendant refused to disclose the name of the patient, because she had left the State, and, without her presence to explain her condition at the time the fetus was taken from her, his answer would incriminate him. The defendant was tried by the board of medical examiners and found guilty and his license revoked. He appealed to the district court, and was there tried and found guilty. From that court an appeal was taken to the supreme court, which reversed the decision of the district court. Justice Harwood dissenting.

Examining the complaint carefully, it will be found that it states that defendant placed in the furnace a headless fetus, with intent to destroy the same and conceal its birth. Conceding that the evidence fully sustains this allegation, there is no unprofessional, dishonorable, or immoral conduct shown. It is well known that premature deliveries are liable to occur through accident or physical weakness of the mother, and at such times the attendance of a physician is necessary. In this case neither the complaint alleges nor the evidence shows that the miscarriage was procured by the defendant, and the law will not presume him to have been guilty of a criminal act. It is quite natural that the defendant should have become possessed of the fetus, and when so possessed of it due regard to sanitary laws required that he should destroy it. There can consequently be nothing unprofessional, dishonorable, or immoral in putting the fetus into the furnace. As to his desire to conceal its birth, such a desire, instead of being reprehensible, is quite laudable and wholly professional, for it is a doctor's duty to preserve secret all knowledge which comes to him in a professional capacity.

As to the second specification in the complaint, which charges that the defendant refused to disclose the name of the patient because she desired that it should not be made public, the question is not whether the defendant was legally justified in withholding the name, but whether he acted unprofessionally, immorally, and dishonorably in so doing. In view of the fact that he believed it to be his duty to withhold this information, until legally compelled to give it, there is much difficulty in

seeing how his conduct was unprofessional, dishonorable, or immoral.

The third charge in the complaint, which alleges that the defendant refused to disclose the name of the mother on the ground that she had left the State, and without her presence to explain her condition at the time of the miscarriage his answer would incriminate him, presents a very nice question for consideration. Were this a criminal trial such a statement could not be taken as evidence against the defendant, but, as pointed out by Justice Harwood, in his dissenting opinion, there is a broad field of human action between moral rectitude and honorable conduct and that of crime, and, while such a refusal to testify could not be used as evidence of crime, it indicates that he seeks to avoid the light of investigation, and thereby casts dishonor upon himself.

There was, however, no specific charge in the complaint of acts amounting to unprofessional, dishonorable, or immoral conduct, nor was any evidence introduced tending to show such conduct. The court was therefore of the opinion that the conduct of the defendant in refusing to give the mother's name was consistent with that of an innocent man made overcautious by fear, knowing that his actions were liable to be the subject of judicial investigation, and that in the absence of the mother he would be unable to show his innocence.*

Effect of Former Adjudication.—It is a well-settled principle of law that a trial and judgment by a tribunal having jurisdiction is a bar to further proceedings upon the facts considered in the former trial; a court would accordingly hold that the trial and acquittal of a physician by the State board of health upon the charge of "making statements and promises calculated to deceive and defraud the public" would be a bar to an investigation by the same body for making "claims and promises which are false and fraudulent," where the evidence in the two cases is identical.†

A trial and acquittal by a medical society is, however, no bar to an investigation under the statute by the State board of health for the purpose of revoking the physician's license. Nor would an acquittal upon an indictment for procuring an abortion act as a bar to a similar investigation by the board of health, the proceedings of the court and those of the medical board being entirely distinct and independent and having different objects and results in view: the one having regard to the general welfare and criminal justice of the State, and the other simply and exclusively to the respectability and character of the medical profession, and the consequences connected with or necessarily flowing from it.‡

Practice in revoking License.—The policy of the law to protect the physician from arbitrary or unjust treatment by the examining board has been considered in connection with their refusal to grant licenses; the same policy to guard against injustice is manifested in cases of revocation of license. Where the examining board revokes the license of a physician without first giving him reasonable notice of the charge against him, and the time and place of the trial thereof, the revocation will, upon appeal, be declared null and void, and the physician will be protected in continuing his practice while the appeal is pending."§

Where a physician is tried by an examining board and

* *State vs. Kellogg*, 11 Mont., 426; 36 Pac. Rep., 357.

his license revoked, and he takes an appeal from the judgment of the board, but continues to practise while the appeal is pending, and is during that time convicted of practising without a license, such conviction should be reversed if his appeal results in a reversal of the order revoking his license.*

Repeal of Statutes restricting Practice.—All statutes restricting the practice of medicine are enforced by penalties prescribed for their violation, and sometimes by provisions disabling the unqualified physician from recovering for his services. It now remains to consider the effect of a repeal of such statutes. As to the criminal feature of such acts, it is a well-settled point of law that the repeal of a law creating a criminal offense renders the law inoperative as to offenses committed before its repeal; if, therefore, a prosecution is pending for the unlawful practice of medicine, and the act making such practice unlawful is repealed, the prosecution must immediately abate. And this rule holds good even if the offender has been convicted but not yet sentenced.

The removal of the inability clause imposed to prevent the collection of fees does not as a general thing enable one to collect for services rendered while such law was in force. This question will be found more fully treated in its proper place in Article VI.

(To be continued.)

Proceedings of Societies.

SOCIETY OF THE ALUMNI OF THE CITY (CHARITY) HOSPITAL.

Meeting of November 9, 1898.

The President, DR. WALTER B. JOHNSON, in the Chair.

(Concluded from page 205.)

The Treatment of Typhoid Fever.—DR. W. L. STOWELL read a paper on this subject. (See page 185.)

Dr. MORRIS MANGES said there were some points he had raised on the subject of antiseptic treatment of typhoid fever in the discussion held two years ago at the Academy of Medicine. He had had occasion to study intestinal antisepsis with some care, and hoped he might be pardoned for repeating some of those remarks. He believed there was already a general systemic infection when physicians began to treat their cases of typhoid fever. The experimental work done by Stern and others showed that the typhoid bacillus was in the blood as early as the seventh day. Antisepsis had demonstrated that the bacilli left the intestinal wall as early as the sixth day. Physicians were usually called to cases of typhoid fever, and made their diagnosis about the fifth, sixth, or seventh day. If it was made earlier than that, there were usually other circumstances which had aided in making the diagnosis. By the end of the first week enough of the typhoid bacilli would leave the intestine and proliferate in the tissues of the body to make the attainment of intestinal antisepsis almost impossible. Even granting that one could disinfect the intestine, enough bacilli would leave it to make the patient as sick as he would be if the intestinal tract was perfectly disinfected. If one took a calomel stool and counted the

number of bacilli in it, one could see that the medicinal effect of calomel was so small that one could allege little for it. Intestinal antisepsis had been tried for certain well-known bacilli, and the stools had been carefully studied both before and after the administration of the drug; and the effect of such administration had been practically nil. Any effects obtained from intestinal antisepsis were probably due to their action upon the bacilli and their local action in checking fermentation.

In regard to the subject of hemorrhage from the bowel, if we could recognize it early enough and call in a surgeon, we might get some results from such intervention, as was shown by Ken's recent work on the subject. For the last six years the speaker said he had been waiting for an opportunity to turn over to the surgeon such a case in Mount Sinai Hospital, but he had not been able to yet. They had had deaths from perforation, but when the perforation had occurred, even with the facilities of the hospital at their command, they had not been able to make a diagnosis early enough in the cases to avail themselves of surgical intervention. If this was true of hospital practice, what hope was there in private practice? In one case of alarming hemorrhage of the bowel he had injected ice-cold water into the rectum with an almost magical effect. The patient would not tolerate surgical intervention, and the result had been gratifying. He spoke of the routine procedure of washing out the lower bowel daily in every case of typhoid fever, whether the patients were constipated or whether they had diarrhoea. If there was no tympanites, ordinary salt water would do, if there was tympanites, one could add whatever remedy seemed best. The addition of a small quantity of quinine might be of service. Another important point was the care of the mouth. Carelessness regarding the treatment of the mouth accounted for many cases of pneumonia and some of the complications that arose in typhoid fever.

Dr. BASER said that Dr. Manges had referred to the futility of attempting intestinal antisepsis after the bacillus had entered the blood, as shown by the presence of the Widal reaction. It was his impression, from reading what Widal and others had said, that the clumping showed a condition of blood deleterious to the bacillus, and that once the bacillus had entered the blood the reaction ceased. It seemed to him that Dr. Stowell had given too high value to this reaction. While it could probably be obtained at some time during the course of ninety-five per cent. of the cases of typhoid, he doubted its establishing the diagnosis in any such percentage. While he agreed with Dr. Manges as to the theoretical impossibility of any such thing as intestinal antisepsis, it had seemed to him that this line of treatment was in practice beneficial, especially as concerned the giving of small doses of calomel. Regarding baths, they had been used too much. If tubing was disagreeable to the patient, and he was excited by baths, they did harm, and sponging, the coil, etc., must be resorted to. In some cases, however, the effect of tubing was most satisfactory, the temperature was reduced to a considerable extent, and the patient fell into a pleasant slumber. With regard to the rectal douche, it certainly worked well, and seemed to ameliorate the effects of the system which the writer of the paper had spoken of.

Dr. ANDREW RICE said that typhoid fever, like many other infectious diseases, was a more trifling than a simple disease. The symptoms and their severity showed up differently in different patients; in some, respiratory symptoms predominated at the start, in others, respiratory

* State vs. Kellogg, 14 Mont. 451, 26 Pac. Rep. 1042.

symptoms; in others, nervous phenomena. We had been told that the supposedly specific bowel ulcerations, etc., might be produced by other intestinal poisons or germs than the specific typhoid-fever germ. Typhoid fever was typical and characteristic in its phenomena, but with a broad margin of variations. There were cases without high fever, and yet with a long, lingering illness. Calomel was an old remedy, and had been spoken of with enthusiasm. In regard to the giving of baths, the cases must be selected; and the element of mental and physical rest must be considered as a factor to determine whether or not they should be given. Opium and its derivatives aided in giving rest, and, judiciously used, the coal-tar products also did so. Alcohol was good for nervous-asthmatic cases. But absolute rest was above all other remedies the best. It was not uncommon to observe that those cases which had been ambulatory the longest time before coming under medical observation were among the worst in their after-course and complications.

Dr. GERRÉAS thought that the giving of baths was sometimes carried too far, or was too generally used. He thought that they should be used only in cases of absolute necessity where there was a high temperature. He spoke of the ice-cap, which would relieve the severe headache when there was a good deal of congestion, which was also beneficial in reducing temperature. In regard to the use of fruit, in his service in the hospital, when typhoid patients were convalescent their friends had brought them fruit, and he did not know of anything that caused rise of temperature so frequently as oranges, when the patient was principally on a milk diet. He did not think that intestinal antiseptics could have any influence on the germs of the disease, but he thought that salol, beta-naphthol, and some other remedies were of great service because, by preventing fermentation in the intestine, they lessened the distress and the tympanites. In regard to a mouth wash, he could speak with a great deal of feeling on this subject, because he had just recovered from typhoid, and had suffered from a very sore mouth. He had found that borolyptol was most grateful and efficacious. He thought the antipyretics were of great value. In his own case phenacetine had worked like a charm, and five grains had reduced his temperature two degrees without having caused any apparent depression. The coal-tar preparations were also of great value in the intense headaches that sometimes occurred in the beginning of the disease.

Dr. W. L. CARR said that the quotations in the paper were very valuable, because they were taken from a writer of whose opinion very much had been thought. The same author made the statement that we must remember that typhoid fever would vary in different epidemics, also that we did not abort the disease, and that we must be rational in our treatment. The speaker thought these considerations were of service, and said they had been verified in his experience. He thought in the treatment they should have consideration for the patient, and not treat the case as a specific typhoid fever. In regard to intestinal antiseptic management, he thought there must be a basis of truth in the use of all the methods that had been carried out and elaborated. He thought the intestinal antiseptic treatment was not always valuable so far as the poison of the typhoid fever was concerned. The toxic condition in typhoid was often beyond control, but there was in the intestine a dimidated, i.e., local action, and under those conditions the intestine was liable to all sort of dangers,

and food which might be very suitable if the intestine was capable of absorbing it, was rather an irritative than a nutritive element. By giving some antiseptics, such as calomel, one might stimulate the liver and intestine, and get some valuable results other than those due to the control of the typhoid poison. In the same way, frequently, rectal enemata were of value, because they cleared out material that would lead to putrefaction, and the patient would be much more comfortable, and assisted in convalescence. In treating the disease he thought one should consider the condition of the kidneys, the heart, and other organs that might be affected either by the poison of the fever or associated poisons. The methods of feeding were of the most importance, and he thought no one could get good results in a typhoid fever case who merely gave medicine. In regard to the use of the coal-tar products, while he would not advocate their being used for any length of time, he did not hesitate to say that they might be valuable and of extreme service in their proper place.

Dr. STOWELL said he had used the combination of these tablets extensively in all manner of intestinal disorders, and he had not observed any marked effect on the typhoid fever. The statistics in favor of tubbing showed that the mortality, which had been from fifteen to twenty-five per cent., had been reduced to two and three per cent.; and certainly it would seem that we were not doing our duty if we did not give our patients the benefit of the tubbing, and yet he doubted if half the physicians present insisted on tubbing for their patients. He stated that it was of very great importance that we should instruct the nurses and the family, and all those who were about the sick, in the exact nature of the disease, and see that no opportunity was allowed for it to spread; that prophylaxis should be applied to the family of the patient we were treating, rather than by getting up a set of rules for the well people.

Book Notices.

Operative Gynecology. By HOWARD A. KELLY, A. B., M. D., Fellow of the American Gynecological Society, Professor of Gynecology and Obstetrics in the Johns Hopkins University, etc. With Twenty-four Plates and Five Hundred and Ninety Original Illustrations. Volume II. New York: D. Appleton and Company, 1898. Pp. xiii-551.

THIS volume is uniform with Volume I in those excellences which we took occasion to commend in the consideration of that volume. In clearness of expression, as to the text, and in beauty and lucidity, as to the pictorial portion, this work leaves little to be desired. The author might have included in his book the subjects of operations upon the mammary gland and upon the gall bladder, two subjects with which gynecologists have had much to do. Certainly they are as much in keeping with his theme in general as hernia and the lesions of the intestine which require surgical treatment.

In this connection the recent remark of Mr. Annandale becomes pertinent: "The distinction between the gynecologist and the surgeon no longer exists."

It is doubtful whether any American will ever publish a more attractive work on gynecology. It is difficult

to see how one more attractive, from all points of view, could be published. The only recent work with which it might be compared is that of Pozzi (we refer to the original work), and Pozzi was not so fortunate in the get-up of his book as Kelly has been.

Traité de médecine et de thérapeutique. Publié sous la direction de MM. P. BROUARDEL, doyen de la Faculté de médecine de Paris, etc., et A. GILBERT, professeur agrégé à la Faculté de médecine de Paris, etc. Tome cinquième. Paris: J.-B. Baillière et fils, 1898. Pp. 995.

The first chapter in this volume, by E. Dupré, is entitled Diseases of the Salivary Glands. About one half of it, however, consists of a general introduction to the study of the diseases of the glandular system. It also gives a general classification of gland infections which is followed more or less closely by the other contributors to the volume.

The chapter on diseases of the pancreas is contributed by Richiardi and Carnot. They regard hemorrhages of the pancreas, excepting, of course, those immediately following trauma, as a peracute form of inflammation, and give an interesting *résumé* of clinical and experimental research into its aetiology.

The section on diseases of the liver was written by Gilbert with the collaboration of Fournier in the chapters treating of symptomatology and diseases of the bile passages and blood-vessels, of Garnier in the chapter on disease of the perihepatic peritoneum, and of Surmont in the chapters on diseases of the liver tissue proper. Although every page of this section shows the changes which in the past few years have revolutionized the views regarding the aetiology of these diseases, the attention of the general reader will probably be arrested most forcibly by the interesting discussion of the pathogenesis of angiocholecystitis and the significance of this condition in the causation of biliary lithiasis and hypertrophic biliary cirrhosis. The classification of cirrhoses adopted by the authors is rather complex and of more scientific than clinical value. It is to be regretted that instead of adhering constantly to the scientific names of morbid conditions they employ so frequently "proprietary" names. "Laennec's disease" is sanctioned by long usage, but why should we be burdened by Hanot's disease and Banti's disease? And as for "Bilharziosis," according to Jean-clème. . . . Some effective method of repressing this form of scientific (?) adulation is urgently desirable.

A short chapter by Lannois treats of the diseases of the spleen.

Abnormalities of the urine are described in a series of chapters by Jean-clème. In the chapter on uræmia, by Chautard, which serves as an introduction to the section on diseases of the kidney, by the same author, there is a good review of the theories regarding its aetiology. Although the adoption of any one of these theories is regarded as premature, the author insists on the theoretical and practical value of "lavage of the blood" in the treatment of the condition. The classification of renal diseases is simple and clinically useful, and the chapter devoted to their consideration constitutes the most valuable portion of the volume.

Common outlines in two brief chapters, the "renal" disorders of the bladder and of the male sexual apparatus.

The diseases of the female genital organs are dis-

cussed by Siredey with reference chiefly to aetiological considerations and their relation to the subject of general medicine.

The volume is distinguished by the same admirable features which have been noted in previous volumes of this work: distinctness of clinical pictures, broad and rational outlines of treatment, and thorough and judicious criticisms of recent advances in medical research. If the views expressed seem at times to be without sufficient warrant, they merit, on account of the authority of their sponsors, respectful consideration. It is a pity that the usefulness of the work should be limited by a very meagre index.

Acromegaly. An Essay to which was awarded the Boylston Prize of Harvard University for the Year 1898. By GRAY HINS-DALE, A. M., M. D., Fellow of the College of Physicians of Philadelphia and of the American Academy of Medicine, etc. Detroit: William M. Warren, 1898. Pp. 88. [Price, \$1.50.]

This essay, like the author's previous one on *Syringomyelia*, published in 1897, is a summary of the facts known and the views held in regard to the rare disease of which it treats. It shows much industry in literary research and a personal familiarity with the subject. The bibliography is the most complete hitherto published.

The illustrations are varied and well chosen and the subject-matter is lucidly stated. Altogether, the monograph will be indispensable to neurologists. If we had any objection to offer concerning it, it would be this: that the author has not sufficiently availed himself of his opportunities of critical analysis; that, to paraphrase a saying of Buckle's, "he has added facts to the subject of acromegaly without enlarging its philosophy."

The Sexual Instinct: its Uses and Dangers as affecting Heredity and Morals. By JAMES FOSTER SCOTT, B. A. (Yale University), M. D., C. M. (Edinburgh University), Late Obstetrician to Columbia Hospital for Women and Lying-in Asylum, Washington, D. C., etc. New York: E. B. Treat & Co., 1898. Pp. 5 to 436. [Price, \$2.]

There are probably few subjects more deserving of frank scientific discussion than the facts and obligations of sexual life. These topics are boldly but clearly discussed by the author for the benefit of lay readers, particularly of adult men, among whom it is to be hoped the book will have a circulation proportionate to its merit and importance.

Diseases of Women: A Manual of Gynecology designed especially for the Use of Students and General Practitioners. By F. H. DAVIS, M. D., Assistant Professor in Gynecology, Harvard Medical School, etc. Third Edition, revised and enlarged. With One Hundred and Fifty Colored Plates. Philadelphia and New York: Lea Brothers & Co., 1898. Pp. xvi + 475 to 394.

AMID the plethora of works on gynecology, with which the profession has been supplied of late in various ways, this work, modest and unpretentious as it may appear, finds a place. It is often convenient for the student to make one's statements in such a form as to be read by those who read them not only for a medical but for a popular purpose, and this the present treatise does admirably well. From the first

page to the last there is not a statement of which the interpretation need be doubtful in the least to one who has ordinary intelligence.

Dr. Davenport has not attempted too much, and here again he has shown the excellence of his judgment; he has not attempted to inform students and practitioners on matters for which they will have little use. He might even have left out the chapter on ovariectomy, and one or two others which appeal especially to the experienced gynaecologist, with no great detriment to his book; but we suppose he may have regarded matters of such importance historically as indispensable in any book which contained any record whatsoever of the gynaecological art.

BOOKS, ETC., RECEIVED.

The Retrospect of Medicine. A Half-yearly Journal containing a Retrospective View of Every Discovery and Practical Improvement in the Medical Sciences. Edited by James Braithwaite, M. D. Lond., Obstetric Physician and Surgeon to the Leeds General Infirmary, etc., assisted by E. F. Trevelyan, M. D. Lond., B. Sc., M. R. C. New Inventions, etc.

ANOTHER ADENOID FORCEPS.

By J. H. WOODWARD, M. D.,

SURGEON TO THE METROPOLITAN THROAT HOSPITAL AND TO THE NEW YORK NOSE AND THROAT HOSPITAL.

EVERY operator of experience agrees that not every case of adenoid vegetation should be managed by the same method. No one supposes that the same instrument is suited to every case. The instrument to which I wish to direct attention, however, will meet the requirements of the majority of cases, I think; and it possesses intrinsic merits of sufficient importance to justify the publication of a description of it.

My first adenoid operation was done years ago with a Jarvis snare. Since then I have operated, as a rule, with some sort of forceps, of which I have tried a variety of models. That which, until comparatively recently, has pleased me most is a small instrument made after the Loewenberg pattern. With that forceps, however, I have been obliged sometimes to strip up the mucous membrane of the pharynx in a most unsurgical manner. It was for the purpose of obviating the necessity of such unsurgical manifestations that I attempted to improve the instrument by giving it a cutting edge and fenestrated blades. With the modified instrument I am able to remove pathological structures from both small and large throats without injuring the normal tissues.

Other cutting forceps for the removal of adenoid vegetations have been in the market during a number of years; but it seems to me that all of them have marked defects. I have undertaken to profit by these mistakes while designing the little instrument which was made for me nearly a year ago by Mr. E. B. Meyrowitz of this city, and of which I am able to present a very fair drawing.

The total length of the forceps is about nine inches. A line drawn from the tip to the joint may be regarded as a chord of the beak's arc (not a segment of a true circle) having a length of an inch and eleven sixteenths. The drop of the handle below a horizontal plane passing through the joint is seven eighths of an inch. These dimensions give an instrument of sufficient length and of suitable form for every case in a person under fifteen years of age.

The blades are fenestrated in the beak. Each fenestra is oval and measures three sixteenths by five sixteenths of an inch. The beak of the right blade passes within the edge of the left blade. The edge of the latter projects inward a sixteenth of an inch from the general surface, so that by virtue of the overlapping of the left blade and the close approximation of the edges of both

58 WEST FORTIETH STREET.

BY SIDNEY V. HAAS, M. D.

It consists of a glass vessel with pouring lip, shaped like a graduate, holding sixteen ounces. The outer surface is divided by vertical lines into seven panels; one panel shows the ordinary ounce graduation; the six others show six different formulae, so arranged as to be suitable for the entire first year's feeding. The following is a more or less accurate reproduction of the arrangement of these panels:

It is possible to obtain other percentages than those shown on the page 4, by mixing what is called for by two adjacent formula, as, for instance, equal quantities

child's growth, accompany the apparatus, which is simple, accurate, and economical, making properly modified milk of practical value obtainable in places where it has hitherto been impossible to get it. The manufacturers of the apparatus are the Surgical and Chemical Supply Company, 147 Centre Street, New York.

Miscellaneous

The Effects of the Habitual Use of Alcohol. According to the *Diabetic and Hygienic Gazette* for January, Dr. Crothers, of Hartford, Connecticut, in a paper read at the New York County Medical Association, October 17, 1898, discussed this subject in a very conservative and intelligent way. He stated among other things that the ingestion of alcohol accelerates the rate of circulation ten or fifteen beats a minute at first, but that after a while the circulation became slower, so that it was actually dropped at least as much as the normal rate, and fell below the normal. As time passed, however, it was gradually considered unprofitable by the organism. The conclusion of the case of his was that alcohol lowered the increase in the pulse rate, and that it was under the influence of alcohol that the pulse rate was lowered. Hallucination, of hearing voices, was also noted.

circumstances. The senses of taste and smell were also influenced by alcohol. The sense of touch was always exaggerated or diminished, and careful measurements of muscular force showed that the muscular system did not escape the deleterious action of this poison. If the temperate man suffered from the use of one or two ounces of alcohol in this appreciable way, then the continual or frequent drinking of alcohol must exert a distinctly deleterious influence. All experimenters agreed that when alcohol was taken in excess the result was a profound tissue and cell degeneration and general starvation of the tissues. Alcohol, by its anæsthetic action, soothed the irritable nerve centres, and the effects were so pleasing that the individual desired to repeat the experience. Often this desire to seek relief by its anæsthetic effect was really an indication of a diseased condition, which perhaps was disclosed only by a post-mortem examination. A century ago the anæsthetic action of alcohol created dementia and idiocy, but to-day it was more apt to cause delirium and paralysis. Heredity seemed to be one of the most prominent causes of inebriety.

The Treatment of Malignant Pustule.—Dr. Castroverde (*Revista de Medicina y Cirugía prácticas*, December 15th) thus sums up his paper on this subject: 1. That the cauterization should be marginal if it is not to occasion much destruction and suffering, as it was practised by the oldtime surgeons. 2. The integrity of the escharotic crust must be preserved, using on it a protective cover to avoid contact with the infectious germs in the air. 3. Bichloride of mercury internally has given excellent results, as have also hypodermic injections of carbolic acid in two-per-cent. solution made twice or thrice daily in the thickness of the oedematous zone and repeated until the oedema has disappeared. The scar is removed by means of permanent irrigation of the pustule with carbolic acid, bichloride or bichromate solutions at a somewhat elevated temperature. By these means perfect antiseptics is maintained.

Indications for Operation in Adenoid Disease of the Nasopharynx.—Dr. James B. Ball (*Clinical Journal*, December 28th) concludes his paper as follows:

"Before laying down some general rules which guide one in advising operation or otherwise in adenoid cases, I may say that not only the cases but the circumstances vary so much that no rules can cover every case. Thus with some patients there is such an excessive desire to avoid an operation, even at some risk, that this may naturally turn the scale in a doubtful case, and then you come across others who seem to be curiously keen to have their children operated on. Sometimes this is due to the exaggerated ideas that have got about on the serious effects of adenoids; but whatever it is due to, it may, of course, influence a decision in an otherwise doubtful case. Then you have a case put this way: How is such and such a symptom to be got rid of? You may think the symptom trivial, and one that will pass off, but the patient will not wait, and beg for an operation. These and other circumstances step in sometimes to influence our decision.

"I will now conclude by enumerating several symptoms and conditions, any one of which by itself may, in my opinion, constitute an indication for operation. Of course, a combination of two or more affords a still stronger indication.

"If there is habitual mouth breathing in a child, which has been going on for a considerable period and

shows no sign of improvement, I should operate. I should include also those children, especially young children, who, though not habitual mouth-breathers in the day, have noisy labored breathing or suffocative attacks at night. In such a case the appearance of a falling in of the lower part of the chest in a young child would considerably strengthen the indication.

"If the child is deaf, or subject to attacks of deafness or earache, or has a chronic otorrhoea, I should recommend operation in all cases, and with a good prospect of cure; but in older children and young adults with long-standing deafness, though I still think we should operate, our prognosis must be guarded.

"Repeated attacks of bronchitis constitute an important indication; so does the presence of asthmatic symptoms. Distinct benefit may fairly be expected in these cases. A constant, persistent cough without bronchial symptoms, not yielding to ordinary treatment, is often cured by removal of adenoids.

"Repeated colds in the head of a severe and prolonged character, or a chronic nasal catarrh, or purulent rhinitis not yielding to simple treatment, may be an indication for operation. Paroxysmal sneezing and hay-fever symptoms are also indications for removal of adenoids.

"There are finally a few maladies, such as nocturnal enuresis, chorea, and epilepsy, where the operation may sometimes be done, although none of the foregoing indications are present, rather with a view to remove all possible sources of reflex irritation than with any distinct promise of direct benefit to the malady in question."

Sanitation under Difficulties.—The *Lancet* for December 31st relates the following story of the difficulties encountered by an English surgeon in dealing with the plague in an Oriental country:

"*Plague in Malegaon.*—One of the most interesting pictures of work in a plague-stricken community appears in a place which at first sight would seem most unlikely for this kind of literature—namely, the pages of a public-school magazine—*The Wykehamist* for December 20th: 'Year by year,' says Kipling, 'England sends out fresh drafts for the first fighting line which is officially called the Indian Civil Service. These die or kill themselves by overwork, or are worried to death or broken in health and hope, in order that the land may be protected from death and sickness, famine and war, and may eventually become capable of standing alone. It will never stand alone, but the idea is a pretty one and men are willing to die for it.' The article referred to is written by one of this fighting line in question, an old Wykehamist, and is a plain, unvarnished record of hard work. The population of Malegaon is mainly composed of Mussulman weavers who wander over the countryside selling their work, and it was by the agency of one of their customers from Bombay who eluded the cordon of guards that plague was introduced. The old Wykehamist set to work with the help of one native doctor who, we are sorry to say, was a venal person. A few days after the outbreak he appeared in a new suit of shiny black broadcloth, which was considered suspicious. Suspicion soon crystallized into certainty when he was caught letting off the family of a rich man from going to hospital, although there was a case of plague. In a week the native doctor was dead. There was no hospital, so they had to convert a rest house situated in the Mussulman cemetery into one, a place which, as the old Wykehamist says with grim humor, was 'very handy,

for the cases usually die in under five days.' Eventually he got an English surgeon to help him who had a rather bad time for the first few weeks, for he was imbued with modern ideas as to stethoscopes and thermometers, which naturally appalled the intensely conservative Oriental mind. However, this wore off, and when the epidemic was over he was *fitted* by the very people who had previously looted his house, and this, too, after having been smitten by the plague himself. The old Wykehamist was obviously endued with the dogged British pluck which a public-school education affords a man. 'I dug up lots of bodies when concealed plague was suspected. Sometimes a body would be left unclaimed in a house and I had to shoulder it and bring it out myself. One day I built a very fine funeral pyre myself and roasted a gentleman.' The *Lancet* adds: "Winchester may well be proud of her son; and the editor of *The Wykehamist* is to be congratulated upon his magazine, for it is certainly superior to the usual run of school journals."

The Value of Thyroid Medication in Fibroma of the Uterus.—Dr. William M. Polk (*Medical News*, January 14th), as the result of a consideration of ten cases of fibroma treated with thyroid remedies, remarks that the net result in each case (Case VII excepted) has been improvement, the greatest occurring in those who have taken the treatment longest. Its manifestations were: (a) Control of the menstrual flow; (b) arrest of the growth and, in some cases, diminution of the size of the tumor and apparently softening of it; (c) disappearance of pain and diminution of tenderness in the growth, and also of the sense of abdominal and pelvic distention; increase of muscular and nervous energy; (d) betterment of general nutrition, manifested at first by slight loss and then by return of flesh; improved state of the skin, hair, and nails, and in the substitution of a good color for the appearance of anemia. As might be inferred, the condition of the bowels was likewise improved, although this was counterbalanced in some cases by gastric disturbances. This was not, however, the sole drawback. There were others, but none was insurmountable—all belonged to the state now designated "thyroidism," but were manifested in its milder form because of the close watch kept upon the remedy. In every instance tachycardia was the most common drawback; next, restlessness and sleeplessness, when the drug was taken at bedtime; and, lastly, indigestion.

It is evident then, he says, that the remedy is efficacious, but when conceded a place, it must be compared with those accepted and now in use. To this end, therefore, he submits the following observations: Ergot, with or without digitalis, has failed to arrest menorrhagia in about fifty per cent. of his cases, and when successful it has been continued, as a rule, in the face of an impairment of digestion and bowel action, interference with the heart's action, and sometimes its use has been accompanied by a good deal of mental depression. Even though retarding growth for a time, it loses this action after a while. It aids in the expulsion of submucous fibroids and the conversion of interstitial into subperitoneal and submucous growths. The general health is apt to deteriorate much in the prolonged use of this drug. The suspension of the ergot has been followed usually by relapse into a state about as unfavorable as when it was commenced. Electricity has given little satisfaction, except when used as a caustic to the mucous membrane of the uterus, and this action has appeared to be

in no way superior to the use of the curette, and is more dangerous. Curettage involves anesthesia and invasion of the uterine cavity not once, but repeatedly in all cases. Ligation of the uterine arteries is an operation *sub judice*, his experience being against rather than in its favor. Removal of the ovaries is an operation which offers, perhaps, a better result than mere ligation of the uterine arteries, but it is an open question with many having a patient fitted for a laparotomy if total extirpation is not better. Myomectomy, either submucous or subperitoneal, and total extirpation are procedures which stand by themselves, facing no rivals in their appropriate fields, so no comparison with any medicinal or hygienic treatment can be instituted with them.

This, therefore, reduces the competitors of the thyroid treatment to the purely medicinal—such as ergot and digitalis—to electricity, and what may be called the palliative operations, such as curettage, ligation of the uterine arteries, and oophorectomy. He recognizes that it is premature to institute a comparison between this thyroid treatment and the so-called palliatives, yet he has ventured upon it for the sole reason that his individual experience has seemed to justify it. If, therefore, the thyroid treatment can be shown to possess the power to keep down the menorrhagia, metrorrhagia, and hydrorrhoea of fibroids; if it can control their growth and annul the pain inherent to many of them, it is superior to any medicinal treatment now in vogue; is better than electricity, curettage, or ligation of the uterine arteries; is preferable to oophorectomy, and in all smaller tumors it should be carefully employed before myomectomy or total ablation is resorted to, excepting, of course, cases in which the growth is merely submucous or in which malignant or septic changes are suspected. All such cases, in common with the larger growths, come within the pale of myomectomy or total ablation and, as already admitted, are outside the field of this comparison.

Blood Enemata in Tuberculosis.—Dr. Whittaker (*Practitioner*; *Canada Lancet*, January) has found marked increase in weight and gain in nutrition to follow the repeated use of blood enemata in tuberculosis. To each quart of blood he adds half an ounce of bicarbonate of sodium and sugar of milk and one grain of common salt. Two pints of a mixture consisting of equal parts of water and such blood are thrown high up in the rectum. Bullock's blood was at one time, the *Practitioner* believes, a favorite remedy in Paris, where patients used to visit the abattoirs in order to get it freshly drawn.

Enucleation of the Ovaries.—Dr. J. Coplin Stinson (*Canada Lancet*, January) concludes a paper on "The Removal of Diseased Ovaries, Tubes, etc., by Enucleation, with Ligation of Vessels only; Forceps as Temporary Hemostatics, Levers, and Tractors, an Addition to the Enucleation Method, as follows:

"From a study of many cases treated by the several methods of operation, I can only draw the following conclusions:

"1. That an irreparably diseased ovary, etc., should be removed by enucleation, with ligation of vessels only; using only absorbable ligatures.

"2. That enucleation is the safest, most scientific and a thetic method of removing an ovarian cyst, tumor, etc., of the ovary, tube, the uterus, etc. There is no danger of hemorrhage, if a vessel is severed; it can be easily and quickly secured by the use of the

"3. That the ligation of vessels only does away with the tying off in sections, the tying and transfixing of pedicles, mass, non-absorbable, dead, and wandering ligatures, sloughing and painful stumps, pelvic exudates, adhesions, and the cautery, etc.

"4. That, as no untoward symptoms follow the enucleation method, there is no secondary operation necessary.

"5. That with enucleation there is little or no danger of injuring adjacent viscera; recovery is rapid, and the danger of sepsis is reduced to the minimum.

"6. That when a Falloppian tube is removed, it should be completely; no stumps should be left. When the serosa of the tube at the tubo-uterine junction is not totally destroyed, it should be divided in a circle about a quarter of an inch from the uterine cornu, dissected back to the uterus, and, after the removal of the tube, the cut edges united by a continuous fine catgut suture.

"7. That in removing an appendage, etc., by enucleation the cut edges of the broad ligament should be united by a continuous absorbable suture.

"8. That even when both appendages are removed, a uterus that is in good position, and not irreparably diseased, should not be removed.

"9. That it must not be forgotten that at times enucleation is difficult. Under such circumstances the surgeon should first separate the adhesions, then enucleate the mass so as to expose the pedicle, which is clamped with long forceps, and then cut across between the mass to be removed and the clamps. The forceps are used as temporary hemostatic clamps, levers, and tractors, while the vessels are ligated separately with fine catgut, and are thus an addition to the enucleation method."

The Three Ages of the Physician.—Dr. N. W. Leighton (*Indian Lancet*, December 16th) says that it is reported of Sir Andrew Clark that he told his pupils that he spent the first twelve years of practice in earning his bread, his second twelve years in earning his bread and butter, and not until the third twelve years could he indulge in luxuries.

Cystitis due to the Typhoid Bacillus.—Dr. Thomas Houston (*British Medical Journal*, February 14th) records a case of cystitis of three years' duration due to the typhoid bacillus, which he considers worthy of record for the following reasons:

"1. The history gives no evidence that the patient ever had typhoid fever, and the fact that she spent so much of her time in hospital and was under medical treatment at home may be held to exclude any possibility of mistake in this respect. In cases of typhoid fever the bacillus of Eberth is often found in the urine, even some weeks after the temperature is normal. This case is one of typhoid infection without the usual symptoms of typhoid fever, and, since there is no point in the history subsequent to the commencement of the cystitis three years ago which suggests the occurrence of a new infection, the probability is that the typhoid bacillus has been present from the beginning. When we consider the fact that typhoid bacilli are so easily destroyed by more vigorous forms, such as Escherich's bacillus, it seems highly improbable that at any time during the course of the cystitis the typhoid bacillus has displaced the colon bacillus in the bladder. The acidity of the urine exclude the probability of other forms commonly found in cystitis ever having been present.

"2. The blood serum gave a decided 'reaction of

infection.' This shows that the case is not a simple bacteriuria, but that the bacillus has a nidus somewhere, as, for example, in the mucous membrane of the bladder, and thereby has such an effect on the blood and tissues as to cause the serum to acquire the agglutinating power.

"3. It seems to follow that in this case the bacillus of Eberth was capable of producing a local lesion without the patient suffering from typhoid fever.

"4. The fact that the bacillus can grow in the tissues without any symptoms of typhoid fever resulting, and produce there a local lesion, is in favor of the view that this fever is a true general infection, and not one of merely local origin, in the Peyer's patches of the intestine.

"5. It also proves that the bacillus may occur in the tissues, and the blood serum give Widal's reaction, without the infection which we recognize as typhoid fever resulting.

"6. To explain the anomalous fact that we have here a lesion, restricted apparently to the urinary organs, produced by the typhoid bacillus, which has persisted for a very considerable time without any symptoms of typhoid fever, three theories seem admissible:

"(a) This patient for some reason or other was not very susceptible to infection with Eberth's bacillus, so that when the opportunity for infection occurred a local lesion alone resulted, and no general infection. This agrees with the result obtained when a non-susceptible animal is inoculated with a given bacillus.

"(b) We have here a form of typhoid bacillus which differs in its infectious power from the recognized form of Eberth's bacillus.

"(c) Typhoid fever is not solely due to the bacillus of Eberth, but other aetiological factors must be brought to bear on the patient before the clinical features of typhoid septicaemia result. The researches of Sanarelli, which show how the virulence of the typhoid bacillus is increased by the injections of the toxine of the *Bacillus coli communis*, and also those of Sidney Martin, which confirm his results, make it certain that the *Bacillus coli communis* may be directly concerned in producing a virulent typhoid infection in animals. In the recent report on the Belfast water supply, Dr. Lorrain Smith has shown that the *Bacillus coli communis* had a distinct relation to the aetiology of the recent epidemic of typhoid fever in Belfast (1898), and that many of the cases gave evidence of the existence of a mixed infection of the bacillus of Eberth and that of Escherich.

"The persistence," says the author, "of the typhoid bacillus in the bladder possibly for three years appears less remarkable when we recall the cases in which abscesses containing typhoid bacilli have been observed six or seven years after the occurrence of typhoid fever in the patient."

A New Chicago Journal.—We have received the first number of the *Western Clinical Recorder*, a bi-monthly of seventy large octavo pages, edited by Dr. Fred Jenner Hodges and Dr. William T. Rinehart. It makes a very creditable appearance.

A New French Journal of General Medicine.—We have received the first number of the *Archives provinciales de médecine*, dated January, 1899. It is a monthly of eighty octavo pages, published in Paris and edited by the indefatigable Dr. Marcel Bandonin. It gives promise of being an important addition to periodical literature.

A New Bucharest Semi-monthly, entitled *Clinica*, has appeared. The first issue, a double number for January 1 and 15, 1899, consists of sixteen triple-columned quarto pages, two of which are devoted to advertisements. It is edited under the direction of Professor Assaky.

The Journal of Tropical Medicine.—This is a new monthly journal which has reached its sixth number, dated January, 1899. The number contains sixty-eight large double-columned pages of reading matter. The *Journal* is edited by James Cantlie, M. B., F. R. C. S., and W. J. Simpson, M. D., M. R. C. P., and published in London.

The Food Value of Mushrooms.—At a recent meeting of the New York Mycological Club Mr. E. H. Gane, a pharmaceutical chemist, read a paper on the use of vegetable fungi as food. He contended that their nutritive value had been much overrated. A great deal had been said, he remarked, concerning the immense amount of valuable food which was daily going to waste in the shape of edible fungi. We had been told that in many parts of the world these vegetables formed the staple article of diet of the inhabitants. Chemists had assured us that mushrooms belonged to the animal rather than the vegetable kingdom, seeing that they possessed a larger percentage of nitrogen than any other class of vegetable life. They were, we were told, essentially "protein" in composition, as much so, pound for pound, as butcher's meat. Two German chemists, Rollmann and Ziegel, had stated, some years ago, as the result of chemical investigation, that mushrooms deserved to be ranked with meat as sources of nitrogenous nutriment. One man in Thuringia was said by Dr. Gautier to have lived upon nothing but mushrooms for thirty years and to have died a centenarian. Comparisons had even been made between mushrooms and other articles of food to the detriment of the latter. Thus, chemical analysis had shown mushrooms to contain from twenty to thirty-five per cent. of "protein," while bread contained only eight per cent., oatmeal ten per cent., potatoes five per cent., and barley meal six per cent. of "protein."

The poorer classes had been urged to substitute vegetable fungi for meat on the ground of their superior nutritive value and cheapness, and farmers had been told that they were neglecting their opportunities in not providing us with more "vegetable beefsteaks." The Department of Agriculture had taken up the subject, incited thereto by publications of the various mycological clubs, and had issued bulletins showing how to cultivate mushrooms advantageously, and how to distinguish the edible from the poisonous varieties.

In spite of all these efforts, the use of the so-called "vegetable beefsteaks" had not made the progress which enthusiasts could have wished, and some doubting Thomases had even cast eyes of distrust on the results of various workers in this field.

As long ago as 1821 a Dr. Kitchener stated in an English publication called *Cook's Oracle* that he did not believe that mushrooms were nutritious. Dr. Joubert in Pereira, in his *Treatise on Food and Diet*, published in 1843, said: "Mushrooms are difficult of digestion, and on certain constitutions act injuriously. Invalids, the peopled, and those with delicate stomachs, will not profit in avoiding the use of this doubtful order of foods." Other writers had expressed similar opinions, not, however, based on experimental work. Dr. Stro-

mer, of Vienna, in 1887, came to the following conclusions as the result of a few experiments:

1. That mushrooms are of small nutritive value, being heavily charged with water, which reduces the amount of nutrient substances.

2. The albumin they contain is difficult of digestion.

3. They are useful as ordinary vegetables, and, being cheap, deserve the attention of the poor.

Mycological enthusiasts had refused to accept these conclusions, and pointed with triumph to the results of chemical analyses, which showed a high carbon and nitrogen value in mushrooms of nearly all varieties. Chemical analyses, they said, could not lie, and no one had ventured to dispute the results obtained.

It was only recently that we had found out that in physiological matters chemical analyses could be found to give results far from the truth. An almost exactly parallel example was found in what had been termed the "brown-bread delusion." A recent writer said:

"For centuries man has wanted white bread for his daily diet. His self-styled 'betterers' have assured him that his daily brown or black loaf, whether of rye, oat, barley, peas, or whole wheat, was much more wholesome."

"About thirty years ago, that 'dangerous thing,' a 'little knowledge' of chemistry, demonstrated beyond all possibility of doubt the superiority of brown bread over white. Chemical analysis, the new infallible Pope of science, revealed that brown bread was far richer in nitrogen than white bread was, and nitrogen was considered the greatest desideratum of all food-stuffs."

"For some reason or other, however, every family, every class, every nation kept discarding brown or black bread and substituting white as fast as they could afford it. The brown loaf still lingers on the board, but rather after the manner of the mummy at the Egyptian feast, a tribute to a vanished ideal rather than an article of food."

Science had again come to our aid and had now proved that, although more nitrogen was present in brown bread, less of it actually got into the blood than from a similar weight of white bread; that white bread was not only more digestible, but more nutritious, weight for weight, than brown. The boasted excess of proteid matter was found to exist chiefly in the husk, or skin, of the wheat berry. This skin in composition was closely allied to woody fibre, and was absolutely insoluble in the intestinal fluids.

An exactly similar condition of affairs was found in studying the food value of vegetable fungi. It was true that the percentage of nitrogenous and carbohydrate matter in the solid constituents of mushrooms was higher than in bread, potatoes, or other vegetables, but, as Dr. Lander Brunton had said, if nitrogen were all we required, regardless of its form, we could grow fat on air. The nitrogen, to be of any value, must be present in an easily assimilable form, and modern methods of physiological research had shown that the nitrogen in mushrooms was very insoluble in the digestive fluids. Professor Mendell, of Yale, in a report to the American Physiological Association on the food value of vegetable fungi, said:

"Chemical analyses were combined with experiments in artificial digestion, and the result was given to the benefit of the human stomach and bowels. The latter was found to be able to extract only a fraction of the nitrogenous matter from the solid ingredients of mushrooms, and the nitrogen was not yet in a form which could be assimilated."

cessories, but they do not deserve the term 'vegetable beefsteak.' Their nitrogen is largely in the form of non-proteid bodies. The amount of fat, cholesterin, soluble carbohydrates, crude fibre, and inorganic substances contained in them corresponds in general with that found in other vegetable foods, such as peas, corn, and potatoes."

The United States Department of Agriculture had also taken up this subject, and in the *Farmer's Bulletin*, No. 79, had published the results of an extended examination into the value of mushrooms as food. The following table showed the relative value of mushrooms and other articles of diet as ascertained by the department's chemists:

	PARTS IN 100 PARTS OF FRESH SUBSTANCES.				
	Water.	Total nitrogen.	Non-albuminous nitrogen.	Protein.	Carbohydrats
Common mushroom (<i>Agaricus campestris</i>)	91.30	0.60	0.24	3.75	3.50
Shaggy coprinus (<i>Coprinus comatus</i>)	92.19	0.45	0.30	2.81	1.40
Inky coprinus (<i>Coprinus atramentarius</i>)	92.31	0.36	2.25
Common morel (<i>Morchella esculenta</i>)	89.54	0.49	0.20	3.06	1.60
Sulphury polyporus (<i>Polyporus sulphuratus</i>)	70.80	0.96	0.31	6.00	3.56
Oyster mushroom (<i>Pleurotus ostreatus</i>)	73.70	0.63	0.33	3.94	4.84
Potatoes	75.50	0.40	0.20	2.50	20.90
Cabbage	92.50	0.18	0.07	1.13	0.70
Carrots	87.50	0.18	0.10	1.13
Wheat bread	35.40	1.52	0.06	9.50	52.80
Beefsteak	63.00	3.00	18.75

Summing up the results of their work, the department stated that the food value of mushrooms was not high. The amount of "protein" contained in them ranked with that of potatoes, and they contained less carbohydrate matter. Further, non-albuminous nitrogen had very little food value, and most of the nitrogen in mushrooms was non-albuminous, while from twenty-six to fifty-nine per cent. of the total solid constituents was indigestible. If, the writer said, a person depended on mushrooms wholly, he would have to consume about eight pounds a day. As a condiment and food accessory they were useful, but as a steady article of diet they were not to be commended.

With a view of ascertaining the correctness of these results, the writer had undertaken a series of experiments. Solutions approximating as closely as possible to the natural digestive fluids were prepared. These consisted of faintly acid and alkaline saliva solutions containing the ptyalin ferment, to represent the natural secretions of the mouth; acid pepsin solutions of approximately the strength of the natural gastric juice; alkaline pancreatin solution; and, finally, a solution of diastase to ascertain the amount of starchy constituents of the fungi.

Typical specimens of the *Agaricus* and *Coprinus* species were procured as representatives of the usual commercial mushrooms, together with one or two varieties of the canned article, the exact nature of which was not ascertained. The digestibility of these in the various solutions was ascertained in various ways. In all cases the fluids were kept at a temperature of 104° F. for twelve hours, in order to approximate the conditions obtaining in the internal economy. The mushrooms were used in the fresh state, after being boiled in water for

an hour, and also after baking over a gas stove until properly "cooked."

As these digestive experiments only approximated natural conditions, the results could at best only approach accuracy, and, consequently, the writer would not attempt to give exact figures. The results might be briefly summarized:

Ten grammes of the fungi were taken in the fresh state, and also after boiling and baking, and reduced to a fine state of division by passing through a No. 30 sieve. The finely divided matter was then digested in a hundred cubic centimetres of the pepsin solution at a temperature of 104° F. for twelve hours. A similar procedure was followed in the case of the other digestive solutions. The results showed that cooking had little effect on the digestibility of the mushrooms, except in the presence of the starch-converting ferments. The amount of solid substance of the mushrooms soluble in pepsin or pancreatin solutions did not, as a rule, exceed ten per cent., and usually varied between five and ten per cent. In one or two experiments the pepsin solution did not appear to have any action on the fungi at all. The saliva solutions seemed to have very little action, not over two per cent. being digested. This, possibly, was due to their dilution. Diastase possessed most activity, particularly on the boiled mushrooms. The soluble portion averaged ten per cent., and in one or two instances ran as high as fifteen per cent. of the total solid contents. In all cases the bulk of the fungus remained undissolved. These results showed fairly well that vegetable fungi were, at least, very difficult of digestion. In a series of parallel experiments with beefsteak and potatoes, the latter almost completely disappeared in about two hours' time, while after twelve hours' digestion the mushrooms remained apparently unchanged.

It was easy, in view of recent researches, to see how the exaggerated ideas of the value of mushrooms as food had originated. The old method of ascertaining the proteid value of foods by determining the total nitrogen and multiplying by 6.25 (the factor obtained from the percentage composition of proteins) might answer well enough in certain cases, but had long since been found to give erroneous results frequently, as in the case already referred to. The text-book statements that mushrooms average thirty-three per cent. of proteid matter, while bread contained only eight per cent., were based on an unfair comparison. The thirty-three per cent. referred to the percentage of solid matter only, while the eight per cent. of bread was based on the total constituents. The percentage of "protein" in the whole mushroom never exceeded five per cent., and most of this was indigestible, while bread averaged eight per cent. in an almost entirely assimilable form. To deserve the name "vegetable beefsteak," the fresh mushroom should contain about fifty per cent. of available proteid matter.

One of the objects of the Mycological Club was to show the public in general the value of vegetable fungi as articles of diet, and it was with the idea of determining their value satisfactorily that the author's experiments had been carried out. The results were not what we had hoped for, but *magnum est veritas et prevalebit*. The fact that the average man had declined persistently to take up mushrooms as food, just as he had declined to use brown bread in preference to white, showed us that "the untutored instinct of the natural man had long since reached the same goal" to which we had been led by the results of experimental research.

Original Communications.

THE X RAY

IN THE DIAGNOSIS OF TUBERCULOSIS.*

By J. RUDIS-JICINSKY, A. M., M. D.

CEDAR RAPIDS, IOWA.

It is difficult to say to what final uses the simple fact discovered by Professor Röntgen that different substances are more or less opaque to the X ray, according to their density, may be put; but one point is now sure, that a very important application of the X ray will be in connection with *early* diagnosis of tuberculosis, and perhaps all diseases of the lungs. Those who have experimentally followed the progress of the X ray since its discovery know very well that its phases have changed from day to day, and are still changing so rapidly that the discoveries, modifications, and different applications hardly could be recorded systematically to satisfy the great interest of our profession at large. Under these circumstances I will call your attention only to the results of my own actual and personal experimentation with *twenty cases of tuberculosis* in different stages, with different data, and different diagnoses, with and without the X ray. I have to state also that any reliable data concerning the infection, arrest of the same, history, etc., can with real accuracy be computed, since no experiment is accurate unless conditions are equal, or nearly so. With the application of the X ray in these cases the conditions were favorable not only for comparison, but for the accurate recognition of the stages of the disease so destructive to the human family.

Keeping in mind that a very large proportion of those affected with tuberculosis may recover their health under proper treatment, or their life may be prolonged, if the diagnosis is made in time, we will find in the application of the X ray in the near future a great help to us, for in this direction lies its highest field of usefulness to humanity.[†] The physician has ever been on the alert to find the beginning of this disease of the lungs; he could not make out the isolated foci and nests of the bacillus in the lungs with his stethoscope, the percussion hammer, or even his valuable microscope, which in the later stages may give absolute proof or may not.

Of the many diseases now known to be dependent upon the presence of some species of bacteria none is of so much interest to the physician as tuberculosis. It wages both open and clandestine warfare, and claims hundreds of thousands of victims every year in this and other countries. How long is it that we have been able,

aided by autopsy and microscope, to fully comprehend the fearful extent of its ravages?

In 384 autopsies of children who died of acute infections in a hospital in Copenhagen in 1894, 195 showed undoubted evidences of tuberculosis. They had shown no signs of the disease in life (*Statistik Danske*, 1895). Such a state presents itself also in this country, especially in the large cities. We know that tuberculosis affects more individuals than any other form of infectious disease, for it has been roughly estimated that out of every five deaths from all other causes, one is due to this cause. We know that tuberculosis is contagious; we know that it is hereditary and due to *Bacillus tuberculosis*; how introduced into the body; how it spreads; how many forms and stages we have. We know also how to discover and prepare the bacillus in later stages of the disease; we have many methods of treatment—some *ne plus ultra*—and the results. That the so-called specific treatment, Koch's method by inoculation with tuberculin or other serum, hygienic and climatic treatment, with environment of the patient, etc., are, so to say, *worthless when applied too late*, when the disease itself was not recognized right at the start, and treated accordingly.

I shall not burden you with a long list of dry details, but give some interesting comparative points of twenty cases in tabular form (with my own radiographs),* collected with care, showing the relation between the usual method of diagnosis and one with the X ray, which shows the degree of accuracy and truth that leaves very little to be desired, as proved especially in those cases where there was a chance of autopsy. My cases have been taken from one district, comparatively healthy, with permanent population, and were collected by me and some of my colleagues during the last two years, give a difference in time, age, and sex only. Please look at the following table, showing the necessary data for our usual diagnosis in those twenty cases, and compare with the diagnosis with the X ray.

At the twelfth triennial meeting of the International Medical Congress, held recently at Moscow, Russia, tuberculosis received a larger share of attention than any other subject presented. And if I am not mistaken, Professor Ilava, well known in pathological anatomy from the Bohemian University of Prague, with other eminent men, during the interchange of experiences from every country and clinic, concluded, pointed out the necessity of *early* diagnosis, and treatment itself should be of value.

As you see, in all our cases the disease, made the usual way was, tuberculosis, and in 18 of those cases went then to San Francisco, Canada, or to Mexico, a few died from the disease, others returned home again, etc. (Table, page 100, next page).

* Some of the radiographs are given in full of detail, which I have not room to present here.

* Read before the Nebraska State Medical Society, Omaha, Dec. 18, 1898, and revised, with additions.

Twenty Cases of Tuberculosis—X-ray Diagnosis (*Pars Secunda*).

Case.	WEIGHT IN THREE MONTHS.			Height.	Girth of chest.	Forced ex-piration.	Forced in-spiration.	Girth of waist.	Number of respirations.	Mar-ried.	How many chil-dren.	Miscar-riages.	Puerper-al sep-tis.	Disease of gener-ative organs.	Men-strua-tion.	Stage.	X ray diagnosis—Fluoroscopic shows:
	1st.	2d.	3d.														
1	110	106	104½	5.1	29	28	30	27	19	No.				Yes.	Irregu-lar.	First.	Slight haziness, indicating the beginning of tuberculous infiltration.
2	123	112	118	5.6	30	28	31	29	17	Yes.	6	2	Once.	No.	Irregu-lar.	First.	Same (accompanied by dullness).
3	134	128	120	5.3	31	30	32½	29½	20	No.						First.	Darkness at lower portion of lungs; pleuritic thickenings; slight haziness at left apex.
4	132	122	106	5.4	28	27½	29½	28½	21	Yes.	2	None.		No.	Irregu-lar.	Third.	Circumscribed spots of bright reflex, surrounded by narrow, dark rings; cavities also in the midst of an area of dense shadow.
5	135	130	129	5.11	29	28	30	28	20	Yes.	None.					Third.	Intense darkness, showing degree, position, and relation of large areas of infiltration, and also consolidated tissue; also isolated foci.
6	169	150	118	6.0	32	31	33	30	19	Yes.							Reflex is abnormally clear, and the movement of the diaphragm is restricted; asthma.
7	Could not obtain.			5.9	27	26	27½	24	21	No.						Third.	Decided shadows on both sides, with circumscribed spot on the left of bright reflex with dark, irregular lines around; cavity in the left apex of the size of a hen's egg. Autopsy corroborated the fluoroscopic picture.
8	114			5.6	27	26	29	26	18							First.	Slight haziness on the right.
9	128	115	110½	5.10	26	25½	27½	26	20	Yes.	1					Third.	Shadows indicating consolidation on both sides, enabling us to recognize more fully and accurately the degree, position, and relation of areas diseased; diminution of the volume of the lungs.
10	129			5.7	27	26½	28	26	19	Yes.	3					Second.	Intense darkness, especially at the lower portion of the lungs, indicating pleuritic thickenings over consolidated tissue, with dark spots on the right and left lobe, especially toward apex.
11	119	106	109	5.3	30	28	31	29	18	Yes.	6	2	Once.	Endo-metri-tis.	None.	Second.	Chesky transformation, with cavities near left apex and opposite upper lobe; opaque to the X-ray in ratio of their density. Cavities not near the surface, not indicating to be near the surface.
12	120	115	109	5.2	29	28	30	27½	20	Yes.	1	2			Irregu-lar.	First.	Slight haziness, indicating infiltration on the left; darkness at lower portion, showing old pleuritic thickening; corroborated by autopsy. Died with tubal pregnancy. Rupture, dead in a few hours.
13	209½	190	170	6.0	36	35	38	29½	19	Yes.	4					Negative.	Lungs normal. Edema of pericarditis giving shadow which was distinct only from the heart shadow by its greater density. Patient, temporarily cured, but has died of a cerebral aneurism.
14	128			5.4	30	29	32	27	18	Yes.	8	2	Once.	Yes.	Irregu-lar.	First.	Dark spots on the left side.
15	138	129	129	6.0	31	29	32½	28½	17	No.						First.	Shadows indicating dark spots on the right side.
16	118	111	110	5.8	37	36	39	30	20	Yes.	8					First.	On the left side, second shadow, which was not so distinct as the first.

Twenty Cases of Tuberculosis (Continued).

CASE.	WEIGHT IN THREE MONTHS.			Height.	Girth of chest.	Forced expiration.	Forced inspiration.	Girth of waist.	Number of respirations.	Married.	How many children.	Miscarriages.	Puerperal sepsis.	Disease of generative organs.	Menstruation.	Stage.	X ray diagnosis—Fluoroscope shows:
	1st.	2d.	3d.														
17	105	5.0	28	27	29	26	18	No.	First.	Isolated foci; spots on the left.
18	123	120	120	5.6	30	28	31	29	18	Yes.	4	1	Metritis.	Irregular.	Second.	Intense darkness on both sides.
19	150	145	140	5.9	37	35	38	30	19	No.	Negative.	No shadow; lungs transparent.
20	137	130	130	6.0	34	33	35	28	19	Yes.	None.	Second.	Dark shadows situated about an inch from apex on the right; dark spots over the area of the left lung nearer the posterior than the anterior surface.

medebitur," it is said very easily. Look at the tabella, pars secunda, and compare the diagnosis made by the X ray.

Since the X rays began their triumphant march throughout the world, our means of diagnosis, not only in surgery, but in medicine, have been greatly enlarged, and some of our methods of treatment changed wonderfully. In our twenty cases, as tabulated, the fluoroscope enabled us to recognize more fully and accurately the degree, position, and relation of areas diseased, giving different shadows of infiltration and consolidation of the lungs, and delineating plainly the limits of those areas. Dr. J. Edward Stubbert, physician in charge of the Loomis Sanitarium for Consumptives, states* that during the year 1897 it was demonstrated that in the Röntgen rays and the fluoroscope we possessed accurate agents for diagnosing tuberculous changes of lung tissue in their various stages. *They were used not only as factors corroborative of results arrived at by auscultation and percussion, but in some instances for discovering isolated foci of infection not recognizable by ordinary methods.*

If we look over the X-ray picture of our table and compare part first with part second, and take also into consideration the statement of Professor Loomis, we must at once recognize the value of the X-ray diagnosis. "Acute tuberculosis, in which there is a dissemination of tubercles throughout the lungs, can not be differentiated by the physical signs. The diagnosis rests later upon an examination of the sputum, but is only of value when a positive result is obtained."†

We have to remember that our cases developed in a vicinity where the climate is healthy and invigorating, dry and tonic, a perpetual foe, as said, to consumption and malarial diseases. The refreshing prairie breezes of summer, the fair and mellow autumn days, the frequent dry and sunny seasons of winter, make up a year of beauty. We can not help thinking under these circumstances, of a direct tuberculous infection only, being unable to find another cause.‡

* *New York Medical Journal*, April 9, 1898.

† Von Jakch state that the bacilli are never present in acute miliary tuberculosis.

‡ Perhaps poor position, heredity or exposure to the bacilli in a dry form in the dust, especially on the well-known windy days.

Billet (*Archives gén. de médecine*, August, 1892) refers, under similar circumstances, chiefly to cases in which the diagnosis of tuberculosis is given up generally in favor of enteric fever, and chiefly because the patient is a little better or perhaps seems to recover. It is among these cases, so to speak, of false enteric fever that the cause must be sought for, and the X ray gives us the best means of diagnosis. In the question of the possibility of the arrest of acute tuberculosis the author refers to the evidence of morbid anatomy which shows not infrequently the healing of pulmonary tuberculosis. There is no reason why tubercle bacilli should not behave like other micro-organisms and fail to develop either owing to unfitness of soil or their own diminished virulence. Abortive attacks of other infective processes are admitted.

Knowing all this, we have to acknowledge that an early diagnosis in tuberculosis means very much, if not everything. It is important to decide whether the adventitious sounds, including subcrepitant râles, which are heard are due to the first stage of tuberculosis, and, when the breathing is harsh in such situation, if there are cavities already, both of which may destroy life, while one is far more difficult to relieve than the other. The X ray makes a positive diagnosis as to this difference. Circumscribed spots of bright reflex surrounded by narrow, dark rings on the plate of the fluoroscope show cavities in the lungs; their adhesions are opaque to X rays and, on the other hand, a slight haziness in the lungs indicates the beginning of tuberculous infiltration. Healthy tissue is transparent, gives the outline of the respective organs, but not a shadow.

While the death-rate of consumption in the past has been appalling, we feel that with the X ray we shall arrive, perhaps, at a better period of its history, when the prophylactic measures, with proper treatment, will begin at an early stage, and its victim is possessed of sufficient vitality or physical resistance to enable the system to rid itself of germs of the disease (Guttmann, Hlava, Bouchard, Maixner, Koch, Brandt, *et al.*).

The most interesting features in our twenty cases form Cases VII, XIII, XVI, and XVII. In Case VII the usual diagnosis of the third stage of tuberculosis was confirmed with the X ray, which gave

us decided shadows on both sides of the lungs, with a plain, circumscribed spot in the left apex, of the size of a pigeon's egg, of bright reflex, with a dark, irregular line around it, extent in direct relation to comparative density of the shadow thrown on the plate of tungstate of calcium of the fluoroscope. The patient died from

Pleuritic thickenings show dark.

Pleuritic Thickenings over Consolidated Tissue.—Dark spots in the field of marked shadow, especially at the lower portion of the lungs.

Emphysema.—The reflex is abnormally clear.

Asthma.—The reflex is abnormally clear, and the movement of the diaphragm restricted.

Pleural effusions are shown in black shadows, the upper level of which may be agitated by succussion.

Tuberculous Infiltration.—Slight haziness in the beginning, enabling us to recognize more fully and accurately the degree, position, and relation of areas diseased. May or may not be accompanied by dullness.

FIG. 3.—Tuberculous consolidation (c).

Tuberculous Consolidation.—Decided shadows.

Cavity.—Circumscribed spot of bright reflex, with irregular line around; extent in direct relation to the comparative density of the shadow thrown upon the plate of the fluoroscope. They may be located also in the midst of an area of dense shadow.

Isolated Foci of Infection.—Slight haziness over small spots clearly defined. Healthy tissue allows the X ray to pass freely, and thus record the location and size of the foci.

Idiosyncrasies are opaque to the X ray.

Simple pleuronic bands are transparent.

Abnormal concretions appear about as opaque as bone.

Foreign Bodies.—Black (metal, lead, etc.).

Destruction of the lung tissue would be distinguishable just as well as any other abnormality in size, etc., from the surrounding shadow, by a line of demarcation, so to say.

FIG. 4.—Cavity. Circumscribed spot of bright reflex (c); irregular surrounding line (f); haziness (f).

It is of interest, from a practical point of view, to note that the application of the X ray in nearly all our cases has yielded good results. This number of experiences and experiments with man, selected from direct practice, go to show that the X rays were accurate

FIG. 5.—Circumscribed spots situated in the midst of an area of dense shadow (g, h).

and very useful for comparative diagnosis, equally applicable in all stages of tuberculosis, as well as the best means of differential diagnosis in nearly all diseases of the lungs.

In conclusion, I would draw especial attention to the simple method of the application of this means of diagnosis, a great advantage in experimenting, and also the best proofs of the same through the negatives, if they could only be developed. This last has been proved by

a large number of investigations on the subject in Europe as well as in this country. I possess, too, an extensive series of experiments on animals, especially rabbits, giving excellent results in radiography, but would not dare to say that the X ray in its undeveloped stage is as yet applicable in every case.

ELECTRO-HEMOSTASIS IN SURGERY.*

By A. J. C. SKENE, M. D.

IN order that you may readily compare that which I have to say about electro-hæmostasis with the accepted methods of controlling hæmorrhage in surgery, I crave your indulgence while I refer briefly to the ligature as a hæmostatic agent.

In looking backward upon the evolution of surgical hæmostasis one clearly sees that the discovery of an aseptic ligature which could be inclosed in the tissues without disturbing the healing process was one of the greatest triumphs in surgery. Such ligatures answered all the requirements of the surgeon so well that he has been disposed to rest satisfied in the belief that the ideal method had been attained. Even at the present time one is liable to be considered hypercritical and fastidious if he questions the utility and competence of the surgery of the day in controlling hæmorrhage in incised wounds. Nevertheless, the modern ligature has its defects and failings when employed in certain operations and in trying conditions.

Catgut as a ligature is difficult to sterilize and keep perfectly clean, and it is not altogether reliable in ligating blood-vessels in the pedicle of an ovarian tumor, for example. More recently I have discovered that catgut is especially objectionable in wounds which are septic or contain necrotic tissue, such as a suppurating ovarian tumor or a pyosalpinx. The broad-ligament pedicle in such cases is nearly always septic, and no matter how clean the ligature may be when applied, it soon becomes contaminated by contact with the diseased tissue, and being dead animal tissue it adds its own substance to the field for the culture of bacteria. A ligature thus contaminated is not absorbed, but acts as a foreign body for the promotion of evil and the interruption of the process of repair, and is responsible for the bad results which sometimes follow in operations done according to all the rules of modern surgery. Others have had similar results, if I may judge from cases which have come to my notice. On this account catgut is the worst material that can be left in a wound which is not perfectly free from germs of disease. Of minor importance, but still worthy of notice, is the fact that dry catgut is not very flexible and easily handled, and if softened by immersion in a sterilized or antiseptic solution it stretches

or breaks, and can not be depended upon to close the blood-vessels and hold them, and therefore hæmorrhage may occur. This has happened in abdominal operations, and on that account many operators, even in the early days of modern surgery, preferred silk ligatures for much of their work.

If I mistake not, the majority of surgeons at the present time use silk ligatures in ovariectomy, hysterectomy, and similar operations; and yet the silk ligature does not meet all the demands of surgery. The objectionable features of silk are that it is not absorbed, but remains in the tissues where it is placed, quiescent in many cases, but occasionally causing much mischief. This has been so fully recognized by some of the leading surgeons that they have raised the question whether this non-absorbable ligature should ever be used in abdominal surgery. Judging from my own observations and the meagre records found in surgical literature on this subject, it appears that silk ligatures either become encysted and remain where they are placed, or, becoming freed from the protecting exudate, wander about until they are thrown out by the eliminative process of suppurative or ulcerative inflammation.

Fine ligatures of silk applied to small blood-vessels in areolar and muscular tissues may remain indefinitely; but those used in abdominal operations are likely to escape into some neighboring viscus. It appears that this harmful action of silk ligatures has escaped observation, owing to the fact that they cause no trouble until long after recovery from the operation in which they were employed. If the silk is clean when used, no immediate disturbance of the process of healing is caused, and so far the silk appears to be a perfect ligature. Still, it is not so, for the necessary walling in of a silk ligature requires more time than the disposal of an absorbable ligature, and the quantity of new material left in the wound surrounding the ligatures retards the process of repair. On this account the tissues in the neighborhood of the wound remain indurated, and do not regain their elasticity and freedom from tenderness for a long time, even when union takes place promptly and without supuration.

Were this all of the evils that can be charged against the silk ligature one might be satisfied; but worse follows their use in pelvic and abdominal surgery. For example, unless the conditions are unusually favorable, the pedicle of an ovarian tumor can not be tied tightly enough to close the arteries in a way to make sure of controlling hæmorrhage with certainty. There is a liability in thick pedicles for the tissues to break under the pressure of the ligature and permit the blood-vessels that have been temporarily closed to open again and permit bleeding to take place.

Whenever the tissues of the pedicle are rendered friable by disease or degeneration, it is well nigh impossible to control hæmorrhage with a ligature of any kind. Silk is as bad as, or worse than, any other, for it cuts the

* Read before the Society of Alumni of Bellevue Hospital, November 2, 1898.

tissues if tied with the necessary tightness. These are the defects which can be alleged against the silk ligature as a means of immediately and permanently arresting hemorrhage.

The subsequent behavior of the ligature and the character of the stump to be repaired after ligation are still more unsatisfactory to both patient and surgeon. The pressure of the ligature upon the nerve tissue, as well as the traction of the parts toward the point of constriction, especially in a short, broad pedicle, cause irritation and pain. There is a large mass of strangulated tissue projecting beyond the ligature which has to be disposed of by a process of degeneration and absorption; the ligature, and the tissue of the pedicle beneath it, have to be closed in by a deposit of plastic material, which in time is removed by absorption and the ligature set free. During all these weeks or months required to complete the repair of the stump there is oftentimes considerable pain and tenderness—nothing dangerous or alarming, but very annoying. Not infrequently, when a diseased Fallopian tube forms part of the pedicle, there is a secondary attack, may be several, of inflammation in the stump caused by the tube remaining open and giving out septic material. These sequelæ have been passed unnoticed by many surgeons, and are lightly spoken of by others, presumably because there was no danger to the life of such patients. But the best operators, who have given attention to this subject and have watched their results with scientific accuracy, have observed these results and recorded them.

This very interesting question of the disposal of silk ligatures has not yet been answered fully, so far as I can ascertain. Guided by my own experience, I believe, as already stated, that ligatures left in the peritoneal cavity as at first encysted and finally liberated, and remain in the peritoneum or escape through some of the viscera.

The last and most important of all the objections to the ligature is the fact that canals (such as the Fallopian tubes, ureters, and appendix vermiformis) lined with mucous membrane can not be closed permanently with any kind of ligature that has ever been used.

Having observed these disappointing actions of ligatures, I naturally looked for something better in surgical hemostasis. This I found in the work of Dr. Thomas Keith, who taught me his method of treating the pedicle in ovariectomy by the clamp and cautery, which in theory and practice was most satisfactory. No doubt this feature of his operating contributed largely to making him the most successful ovariectomist of his time. The experience of years and a large number of operations in which this method was used has fully confirmed my confidence in this way of controlling hemorrhage. The method was never adopted by surgeons, however, owing, in part, to ignorance of the principles of the method, but more especially to the difficulties in the technique of the procedure. Many believe I, and still believe that it is necessary to char the stump with the cau-

tery in order to stop the bleeding; but the fact is that Keith applied a clamp with broad jaws to the pedicle, and compressed it strongly, and then applied a large cautery iron to the upper side of the clamp until the instrument was heated sufficiently to desiccate the tissues, but not to char them. This required much time and large experience in handling the cautery iron in order to obtain the degree of heat necessary, and to know the length of time it should be applied. In other words, to treat a broad-ligament pedicle in this way required a knowledge and judgment that but few had the patience to acquire.

I confess that I was not sure of my work in my first operations with this method, and when ovariectomy became improved so that better results were obtained and materials for ligatures were made aseptic and more appropriate, I gave up the clamp and cautery and used the ligature; but I was never satisfied with the results, and earnestly sought to overcome the objection to the clamp and heat to control hemorrhage. While thinking of how to overcome these difficulties my attention was called to the use of electricity in heating laundry smoothing irons. It then occurred to me to adapt the same heating power to surgical instruments, such as the clamp and forceps.

My requirements in this regard were explained to Mr. Louis M. Pignolet, who soon produced the instruments and appliances required, which I shall now show you.

Directions for Using the Electrical Forceps.—The method of arresting hemorrhage with these forceps consists in firmly compressing a portion of the bleeding tissues, or the end of a blood-vessel, between the jaws of the instrument, in order to expel as much of the moisture as possible, and then desiccating the compressed tissues by heat generated in the jaws by the electric current. In this way the walls of the arteries become united and hemorrhage is effectually prevented. The temperature required for desiccation is from 180° to 190° F., which is high enough not to char or burn the tissues, but simply to desiccate or to cook them.

The current required to heat the smallest instrument is two amperes and eight for the largest, at a pressure of three volts and a half.

The forceps are sterilized in the same manner as other instruments. A little sterilized vasoline, or similar preparation, is rubbed over the inner side of the jaws of the forceps, which will prevent the tissues from adhering to the instrument.

The rubber-covered end of the electrical cable is sterilized in boiling water and afterward wrapped in a sterilized towel, or immersed in an antiseptic solution, such as a five-per-cent. carbolic solution, until needed. Bichloride of mercury should not be used, as it attacks the metal sleeves at the end of the cable.

In applying the forceps all the tissues to be treated should be firmly compressed between the heated jaws of

the instrument, for if a portion extends beyond, a second application will be necessary. Before the electric current is turned on a shield is applied, where needed, between the forceps and the adjacent tissues to protect them from injury by contact with the hot instruments. Tissues which do not touch the jaws require no protection.

The two connector sleeves at the end of the flexible cable are then slipped over the two terminals on the end of the forceps and pushed firmly into place to make a good electrical connection. If the electric current has been previously turned on, the putting of the connector sleeves into place completes the circuit and establishes the current.

The current required to properly heat the forceps is noted for each one made; therefore it can be regulated to suit the forceps from the indications of an amperemeter included in the circuit to measure the strength of the current. If no amperemeter is convenient, experiments upon a piece of raw tissue will enable the operator to ascertain the temperature by the sense of touch and examination of the tissue.

One adjustment of a transformer or of the rheostat of a storage battery will be sufficient, if the same adjustment be made in subsequent operations; but the battery should not be used when its charge is nearly exhausted, if uniform results are desired, unless an amperemeter is employed. For the same reason the transformer should be fed by an electric-light current, as this has an almost constant pressure, and not by one used exclusively for power, as such a current is subject to considerable change of pressure. An amperemeter should be used with the ordinary primary battery, for the polarization and the varying strength of the exciting fluid prevent it from being adjusted so as to furnish a current of uniform strength.

Before removing the forceps, the tissues projecting beyond its jaws are cut off, which may, in some cases, be done while the heat is being applied, in order to save time. There being danger of losing sight of the stump by its dropping back into the abdominal cavity, as may happen in ovariectomy, the shield forceps should be left in place to hold the stump for inspection. The electrical forceps is then carefully opened far enough to allow the desiccated stump to slide out from between the jaws in the direction of the teeth. Care in this is important, for, if the tissues should adhere to the instrument, which may happen if vaseline is omitted, they might be torn apart, and a ragged stump left.

Before using the forceps for the first time, it is instructive to experiment with them on a piece of raw tissue so as to become familiar with their action, as well as to ascertain whether the source of electricity is suitable and can be properly controlled.

Absence of bleeding upon the removal of the forceps shows that the desiccation has been effective, and the stump can be left without fear of secondary hemorrhage.

The occurrence of bleeding immediately upon the removal of the forceps indicates that the desiccation has been insufficient, or that some of the tissues have escaped the grasp of the forceps. In this event one should reapply the forceps to the stump and repeat the heating, giving about ten per cent. more current, or continuing the heat for a longer time, if the bleeding has been due to insufficient desiccation.

The time required for desiccation varies from half a minute to two minutes, according to the thickness of the compressed tissues or size of the arteries; two minutes being required for the ordinary ovarian pedicle and the broad ligament. If the tissues to be treated are very thick, the current can be continued for three or four minutes, or even longer, without danger. When the time of application has expired the current can be shut off by a switch, or by removing the connector from the forceps. The desiccation can be hastened by starting with more than the usual current and continuing the greater current for about a third of the time of application. For example, if the current necessary to properly heat the forceps is *ten amperes*, and the time of application is two minutes, give *twelve amperes* for about forty seconds, then decrease to *ten amperes* for the rest of the time.

It is well to begin with the forceps closed on the first notch of the lock, and, after the heat has been applied for about half a minute and the tissues have begun to shrink, to close the instrument fully. In this way the greatest possible compression of tissues is obtained.

In the treatment of isolated arteries, the end of the blood-vessel is grasped by a tenaculum and the electric artery forceps applied cross-wise; or the artery is seized by the electric forceps in the same manner as with an ordinary artery forceps when a ligature is to be used.

The end of an artery or the stump of a pedicle when thus treated resembles parchment in gross appearance. The thickness depends upon the size of the blood-vessel or mass of tissue treated. A large uterine artery is reduced to about a line in thickness and an ordinary broad-ligament pedicle to less than an eighth of an inch. The part is translucent and structureless, and thus enables the surgeon to tell at a glance when the treatment is incomplete, by observing the blood-vessels that remain unclosed, and that the pressure and heat should be applied to complete the hemostasis.

Occasionally, in treating a thick mass of tissue, the central portion of it becomes heated before being fully compressed, and then the blood is coagulated in the blood vessels and leaves dark strips or central staining of the tissues, which causes some opacity of the parts. As a rule, however, the blood is pressed out of the blood-vessels before the desiccation begins, and the stump is sufficiently translucent to enable the operator to see any blood vessel that has escaped. The indications or requirements for closing blood vessels are in this way thoroughly fulfilled by the complete fusion together of the

walls of the blood-vessels so that they do not, in fact can not, come apart. This I have demonstrated again and again. While I found in all my observations that the hæmostasis was immediately complete, I was suspicious that when the tissue became softened by absorbing moisture, the blood-vessels might open up, and subsequently bleeding might occur; but many clinical experiences and experiments by others have settled that question beyond all doubt.

Results of this Hæmostatic Process.—Dr. R. L. Dickinson placed a mass of tissue, one part of which was treated by this method, in non-sterilized water and let it remain immersed for about seventy-two hours. At the end of that time the tissue not treated was a soft, pulpy mass that broke down under pressure of the fingers, while the desiccated portion remained firm, though somewhat softened by the water, but with no separation of its component parts, and he could not find any part where cleavage or dissection could be made. I have repeated this experiment many times with the same results.

Finally, I may state that I have employed this method in over two hundred celiotomies and in many vaginal hysterectomies and other operations, and have never had secondary hæmorrhage in any of them.

These are the facts regarding the method as a hæmostatic. There still remains the question of the subsequent behavior of the ends of the blood-vessels and the tissue thus treated; in other words, the process of repair.

From all the facts that I could gather on this subject in actual practice, I concluded that the desiccated tissue became first hydrated and then reorganized, and remained as permanent structures, closing for all time the ends of the blood-vessels, lymphatics, and canals so treated. There was still uncertainty on this point, until Dr. W. H. Seymour, the pathologist to my department in the college, conducted a series of independent experiments in the Hoagland Laboratory. The account of these observations and experiments by Dr. Seymour is as follows:

On examinations made immediately after treatment, he observed that an artery a quarter of an inch in diameter was reduced to about a twelfth of an inch in thickness, and that the structure of the tissues was rendered amorphous by the heat and pressure. The lumen of the artery was obliterated completely, so that no trace of its original structure could be found. A piece of tissue containing arteries, nerve fibres, and muscular and areolar tissue presented the same amorphous appearance, and complete closure of the arteries. So completely fused together were the luminal walls of the arteries that no trace of the original structure could be found; neither could the lumen be reopened by testing the microscopic specimen. Observations were made of sections of the Fallopian tubes, the appendix vermiformis, the ureter, and other canals lined with mucous membrane, and the same amorphous conditions were found. The character of the mucous membrane was so completely

changed in all of them that no part of its original structure could be found by microscopical examination.

The following observations were made on two stumps taken from canine subjects following laparotomy at the end of the third and tenth days of the healing process:

In each instance, prior to the application of the forceps, careful antiseptic measures were followed out in the exposure of the tube and uterus. The hæmostatic forceps of the smallest size was placed on each stump, and an electric current used for one minute of sufficient strength to raise the temperature of the forceps to 180° F.

Microscopical examination three days after the operation showed, at the point of application of the forceps, a constriction corresponding in width to the forceps, on the surface of which were numerous corrugations which corresponded to the same in the blades of the instrument. A decided compression was shown to exist at the point of application, and also a quantity of recent lymph and solid exudate was found over the free end of the stump. Considerable ecchymotic hæmorrhage was noticed at the uterine end of the area treated with the hæmostatic forceps. The free end of the tube was seen to be softened, and it corresponded in appearance with what might be expected in the earlier stages of coagulation necrosis.

On an examination of the luminal portion microscopically, the canal of the tube was seen to be obliterated.

Microscopic examination of a transverse section, under the low power, showed the mucosa and submucosa to be in apposition, no distinct line of demarcation (luminal) having been apparent. Considerable softening existed in the outer portions of the wall of the oviduct. The small round cells could with little difficulty be traced far back into the muscular layers of the organ.

Under the high power were seen countless small cells of the reparative process, intermingling with which were also fine fibrous elements surrounding small and large areas of coagulation necrosis. On studying the luminal portion of the mucous membrane, the small, round cells of one surface seemed to merge or blend with those of the opposite, thus preventing the recognition of the luminal margin of the mucous membrane.

The specimen removed at the end of the tenth day of the healing process macroscopically resembled in its treated portion that of the third-day specimen; the treated area, however, was much duller in outline, firmer over its end, and contained much less softened material and lymph than in the former specimen. The lumen could not be macroscopically identified.

The microscopic appearance of a portion of the oviduct taken through the lumen and mucosa, longitudinally, at the point of application of the hæmostatic forceps, represented marked areas of coagulation necrosis, together with some hæmorrhage by diapedesis, shown in adjacent neighborhoods.

The mucosa of the two walls of the tube were seen to be in contact, thus producing actual obliteration of the lumen of the tube, due to active proliferation of the cells of the mucosa and infiltration of small, round cells.

The advantage which may be fairly alleged for this way of controlling bleeding in surgery is that it is certain and reliable in closing isolated blood vessels or those imbedded in masses of tissue, like an ovarian tu-

mor or pedicle, for example. At the same time that bleeding is arrested, all lymphatics are sealed up, which prevents septic absorption. The tissues of the stump are reduced to the smallest possible size, and there are no raw surfaces left to form adhesions to the abdominal or pelvic viscera, or any foreign substance left in the tissues to cause mischief.

Tissues which have become friable by disease and can not withstand sufficient pressure of a ligature to control bleeding are easily managed by this method. When the tissues that form the pedicle of a suppurating ovarian cystoma or a pyosalpinx contain septic germs, a condition in which the ligature is most objectionable, a better and much safer stump can be made in this way. Bleeding vessels in the abdominal and pelvic cavities can be reached and closed with greater facility than by ligation.

Nerves that accompany the blood-vessels are immediately devitalized, and hence there is less pain and irritation in the stump. The heat employed sterilizes the parts involved, and therefore the operation is perfectly aseptic. To these many advantages may be added that it leaves the stump of a pedicle or the end of an artery in a condition requiring the least reparatory care, so that recovery is more prompt, uneventful, and complete.

THE AMBULANCE SERVICE IN THE WAR.

By MAJOR JAMES JOHNSTON.

SURGEON SIXTEENTH PENNSYLVANIA VOLUNTEER INFANTRY;
LATE SURGEON IN COMMAND, AMBULANCE COMPANY, FIRST DIVISION, FIRST
ARMY CORPS; SURGEON IN CHARGE, DIVISION HOSPITAL, CAMPO, P. R.;
ACTING CHIEF SURGEON, FIRST BRIGADE, FIRST DIVISION, FIRST ARMY CORPS,
BRIARFIELD, PA.

UNDER the provisions of the international treaty known as the Geneva Convention, all hospitals in the field, all ambulances, and ambulance trains must be absolutely in charge of medical officers. They must be honestly used for sick and wounded men only, in order to entitle them to exemption from attack, and must not under any circumstances harbor combatants, or be used by field or line officers for any purpose whatever.

It is only in case of necessity that ambulances may be used to haul food or medicines for the sick, and neither ambulances, nor the medical officers, nor the members of the hospital corps can ever properly assist the army in its active operations in the field. They are all subject to capture by the enemy, and the property may be held as any other property, but the occupants and attendants are to be cared for and permitted to return as noncombatants.

The United States Government has not had use for an ambulance service constituted on international lines until the time of the present war.

The idea of a systematic ambulance service, in American use, having originated with Dr. Jonathan Lettermore, of the Army of the Potomac. It has been adopted by the armies of nearly every civilized nation

and is credited with having done more than anything else to alleviate the horrors of war. But with us there has not until now been occasion to do more than study foreign progress and plan how we would profit by it when necessity required. At the small posts of our regular army there has never been use for more than one ambulance, and the animals for that have been borrowed from the quartermaster on the days when it was taken out for drill.

For this war a complete and elaborate plan was arranged. Orders were issued early in the season providing each army corps of three divisions with three division hospitals and a fourth to be known as the reserve; also for each of its three divisions an ambulance company, together with a fourth, also known as the reserve.

The events of the war having been precipitated in advance of the formation of the army, and especially of the medical department, these plans were never fully carried out. No hospital and no ambulance company was fully equipped, neither were they properly manned, and in most cases the medical officers were simply staggered by duties not in the line of their professional work, with which they had not the least preliminary acquaintance.

The printed orders described hospitals to the extent that they were to be managed by six surgeons, six hospital stewards, and ninety privates, and the ambulance companies were to have each six surgeons, seven hospital stewards, and one hundred and four privates.

The First Army Corps, commanded by Major-General Brooke, was encamped as a whole at Chickamauga from the latter part of May to the early part of July, little more than a month, and during that time it came nearer to reaching a condition of completeness than any other corps in the army. The amount of labor performed by these troops during this time was prodigious. Officers and men, all volunteers, worked day and night. In every case in which action was required it was necessary first to learn how to do it, and then to get it done. Quartermasters and commissaries, as well as medical officers, had to learn by experience, and their failures always made trouble for others as well as for themselves.

It is extremely interesting at this time to recall the words of Colonel Charles R. Greenleaf, spoken at the meeting of the Association of Military Surgeons held in St. Louis in 1892: "The practice of medicine and surgery in military life does not differ from their practice in civil life, save in the circumstances which surround them. The ever-present necessity with the medical officer is a comprehensive knowledge of military affairs. No other officer of the army is required to be individually familiar with the duties of every other military department in addition to his own, and yet this is the task which the military surgeon is called upon to perform. He wishes to be successful in his duties in the field."

"Imagine, if you will, that it were to-day at war with a foreign nation, and that the army of occupation in

the field of one hundred thousand men. That army is necessarily made up of members of the National Guard, for in time of war the regular army is but a nucleus or color guard of the fighting force. The administration of its medical departments consists of two thousand six hundred officers and men. Under ordinary circumstances five per cent. of the command, or five thousand men, are constantly sick or wounded, while after a battle the non-effective list is swelled to ten per cent., or ten thousand men. An accident of date of commission may make any one of you gentlemen the medical director of the force. What would you do after reporting to the commanding general and finding yourself face to face with the responsibilities of such a position?

"There is no time to learn and no one to advise with; each branch of the service has all it can do for itself, and you are practically alone, with the knowledge that each day of unaccustomed field life will, slowly but surely, add to your minimum of non-effective sick. You also know that there must quickly be a fight, involving the necessity for the care of an additional ten per cent. of wounded. The efficiency of that army, the care of its sick and wounded, and your own reputation, depend on your doing the right thing *then and there*.

"If advantage has been taken of the opportunity furnished to all surgeons of the National Guard for thoroughly learning all these comprehensive duties, you will find that familiarity with those of an adjutant will enable you immediately to establish order through a record system; to secure needful shelter by correctly preparing the necessary requisitions upon the quartermaster; to secure proper food in a similar manner from the commissary; to properly place and regulate the men of your hospital corps as any regimental or company commander would do; and finally, to preserve discipline, and so co-ordinate the several military systems that all shall work as one harmonious whole under the experience of your training as a commanding officer.

"Our system of property accountability is such that nothing can be had unless formal requisition is made for it, and the 'how to do it' is the *open sesame* to military as well as to any other success. No words of mine can possibly give you an idea of the confusion, the delay, the damage to property, and the loss of life that follow the work of the man who only knows 'how not to do it.'"

How far the warning conveyed in this prophetic picture was justified is now a matter of common knowledge. Yet I believe that it is a fair criticism to say that the colonel over-estimated the character of the experience to be gained in the National Guard. He says in another place, "We envy you of the National Guard your opportunities." For myself, I can say that I have served in the National Guard of Pennsylvania, which he particularly praised, for six years; that I have had the fortune to be surgeon of the regiment which has had more experience in active service, on duty at strike and riots, than any other in the United States—a total of one hundred

and twelve days since I have been with it, in addition to regular encampments; and yet when I found myself in the army, it appeared to me that I knew nothing at all.

I was not acquainted with the paper forms of my own department, much less with those of the quartermaster, commissary, and ordnance departments. I did not know that we would be taken from our regiments and have to command and care for men of the hospital corps in camps apart from those of other commands. I did not know that we would have to care for patients further than to obtain supplies of medicines and prescribe for them. I did not know where the duties of our department ended and the duties of other departments began.

We borrowed men in the National Guard from the companies, and the captains took care of them in all matters connected with quarters, rations, clothing, and pay.

The men, the canvas and cots, the wagons, the mules and ambulances, the kitchens, the cooks, the camp itself and all connected with it, everything in or about a hospital or an ambulance company, the drilling, detailing, and court-martialing of men, these and a thousand other things doctors have to busy themselves with in the United States service, and all simply incidentally and preparatory to taking care of the sick and injured.

In the First Army Corps, as I suppose in every other, the division hospitals were not organized and equipped for work before being thrown open, as one might say, to the public. They simply grew up in accordance with the necessities of the troops. These necessities of the men were from the start out of proportion to the preparations made for the care of them. Especially, there was no opportunity to train men for their duties as nurses, but anybody and everybody available had to be made use of as fast as they could be obtained. Those who could do the work were forced to work overtime. Those who could not had to do the best they could anyway.

The reserve hospital for the First Army Corps was not used for patients. It was built as a model, and a strong effort was made to use it as a drill ground and school for officers and men; but the demands of the sick, which exceeded all anticipations, together with the difficulty in recruiting men for the hospital corps, made it only a partial success.

By all surface indications, Chickamunga Park is an ideal place for a large encampment. Open fields alternate with open woods, in which delightful camps may be made. The valley of Chickamunga Creek is broad, shallow, and high above the neighboring valley of the Tennessee River. The soil is clay, with only the thinnest possible layer of loam upon it wherein the malarial germ may reside; and it is overlaid with limestone in which good water is had by drilling from forty to one hundred and twenty feet.

No one could have foreseen that new regiments, representing the robust health and vigor of the nation, each individual fresh from a close medical examination,

would show a considerable sick report from the beginning in such a wholesome locality. There was no typhoid there; but it appears to be true that certain regiments brought it with them from their State encampments, and that it reached the wells from the sinks, and in this way infected the camp.

The ambulance feature of the medical department at Chickamanga was begun in a more deliberate manner than were the hospitals.

The reserve company was formed first, and while its camp was made the depot for all supplies, it was built up in excess of its proper quota to be the parent of the ambulance companies of the divisions.

The total number of regimental surgeons in an army are three to a regiment, and these have to be divided up to fulfill the consolidated duties.

In three divisions there are eighty-one surgeons, forty-eight of whom are assigned to four hospitals and four ambulance companies, six to each. One remains with each of the twenty-seven regiments. His duties are those of a sanitary and hygienic officer. With a hospital steward and a private of the hospital corps he maintains a dispensary, but he is not expected to take care of any sick. Only six of the eighty-one are not especially assigned, which gives a small force available to fill vacancies and help out where needed.

It was the writer's fortune to be assigned to the task of organizing the Reserve Ambulance Company of the First Army Corps, an organization that will always have this degree of interest attached to it, that it was the first and only one of its kind to attain its full growth, all the others being cut off in the bud by the cessation of the war.

Hospitals may be busy in times of peace, but the existence of an ambulance company depends on the prospect of battle. An ambulance company, with a total of one hundred and twenty officers and men, has eighteen ambulances and sixteen wagons. All of the men are either mounted or entitled to ride. For duty in the field, it is accompanied by its corresponding hospital with its total of one hundred and six officers and men. The baggage, supplies, foods, and cooking outfit are loaded in the wagons. The medical officers of the hospital, as well as those of the ambulance company, are mounted, and each one has in attendance a hospital steward mounted on a mounted orderly, who carries a large pouch full of instruments and dressings. The men of the hospital are divided. Some remain with the canvas to set up, others go with the ambulances as litter bearers. If a company were operating by itself, this would be a small detachment of the medical force, and it would be subject to division into sections for hospitals, under orders of the division chief surgeon; but in case of a battle, in which the whole corps is engaged, then there would be available for duty four times the force. It would be expected that more than one division would be engaged at one time. It would have it even for a while

would do all the work, if it could. Then the reserve company would be at hand, and, in addition, the companies of the other two divisions, or such portions of them as might be spared, would strengthen the reserve, and there would be a possible total of seventy-two ambulances on the line.

The litter bearers would go actually on the line of fire and remain there. The ambulances would go as close as the practicability of the roads would permit, maintaining a regard for shelter when possible, and due precaution also against the possibility of capture.

The hospital would be far enough in the rear to be safe from the longest shell fire and behind the strongest fixed line. It is the chief aim of the medical department at the present date to get men away from the front as quickly as possible, and as far as possible, after they are wounded in action. For this reason its chief agent is the ambulance companies. Modern bullets as well as modern surgery combine to make this chief aim proper and successful. There is very little need of operative surgery on the firing line. Ambulance surgeons are supplied with the operative equipment, but it is mostly used in the rear. The first surgical requisite in any kind of a wound is a clean first dressing, which may be very quickly applied. Then a comfortable journey to the field hospital, where clean hands and quiet nerves with aseptic surgery will make good any injury that is not immediately or necessarily fatal.

It is a distinct advantage for the medical department that it is given its own transportation. It does not wait now for a battle to be decided, and for the needs of the well men to be supplied before it is able to accomplish its work.

Before the formation of ambulance companies, the ambulance wagons were under the control of the general officers, and depended on the quartermaster's department for motive power. The history of most of our great battles in the civil war is that ordnance, commissary, and quartermasters' wagons were brought up in advance of the ambulances, so that it was often several days before the wounded were taken of the field. Now, an ambulance is privileged to go right up to the firing line, and follow it back and forward, waiting to be used for its own proper humanitarian purpose, when it goes and returns at will, through all lines and at all times, as may be necessary.

This is in brief the theory of the ambulance service. It is enough to show that success depends on a thorough organization and discipline, and that it is well planned to render such efficient aid that no one would regret at any time unpatriotic, but each man of the service will be rapidly removed under proper conditions of transportation to the hospital in the rear.

There were a considerable number of ambulances in the First Army Corps, and it was expected that they would be put to use in the war. It was expected that they would be put to use in the war, to that extent were they.

But the writer was relieved of the command when his regiment was ordered away, in accordance with the policy of the department, which kept all of the volunteer officers and men as closely as possible with their own organizations; and it was his further good fortune to be in command of a brigade section of a division ambulance company which did have an opportunity—two opportunities—to demonstrate its usefulness in Porto Rico.

The story of the military operations on this island is short and well known.

The Sixteenth Pennsylvania Volunteers, as the advance of the First Brigade, First Division, First Army Corps, followed the Spanish garrison of Ponce until it made a stand and was captured at Coamo. The balance of the brigade, consisting of the Second and Third Wisconsin Volunteers with the Brooklyn troop of cavalry, companies of the Third, Fourth, and Fifth United States Light Artillery, General Ernst's staff and train, and the field hospital, remained at Ponce until the fact of the stand at Coamo was ascertained. Then it was all packed up, and at the end of three days of forced marching it passed ahead of the Sixteenth, and encamped within four miles of the village.

The ambulance company had an existence as a part of the brigade, and had a camp along with that of the field hospital, but it spent most of its time on the road, making daily calls on all of the different organizations, following them in their movements, and carrying back the sick to the hospital at Ponce.

When our brigade came in sight of Coamo the citizens appeared on the hilltops as though to see a circus. We had passed the Sixteenth about two miles behind. During the night it marched off to the left, by a bad mountain trail, to flank the Spaniards and reach their rear. Their outposts had already reconnoitered our ground up to a blockhouse occupied by the enemy, which was to be our point of attack.

Next morning our whole force, artillery, cavalry, and infantry, moved from camp along the roadway to a point in plain sight of the blockhouse and eighteen hundred yards from it. The field pieces were lined up in a meadow, and deliberately began target practice at the blockhouse. The range crossed a valley in which was a sugar refinery with its clustered outhouses and residences.

The air was still, the fields neatly kept and of a beautiful green color, the high hills shaded into blue at their tops, and the entire scene, in the bright but mild sunlight, was far more suggestive of joy than of warfare.

But immediately after the first shell had exploded in front of the blockhouse, and partly hid it from our view with white smoke, there came a reply with Mäusers, which sufficiently indicated the character of its occupant. We realized that we were under fire and that an engagement had commenced.

The Spanish fire was not effective. It soon grew feeble and ceased. The rapid succession of shells from our guns was too much for the few who were there. In

about twenty minutes the house was on fire, and they scattered away.

Then the cavalry and the Third Wisconsin moved ahead to the right. The Second Wisconsin in long double ranks swept slowly across the intervening fields to the plantation buildings, beyond them to the ford, its thin blue line glistening with steel slowly crossing the cultivated fields where only the corn-cutter's machete had gleamed in the morning suns of over four hundred years.

The artillery took up an advanced position, still directed to the blockhouse, in order to be ready in case that our skirmishers should find its trenches to be yet occupied.

The ambulance company had been left in a sheltered position around the last turn of the road. It was now divided. Two medical officers, with the drivers and orderlies, together with a dozen litter bearers, remained to follow with the ambulances. Taking with myself Lieutenant W. G. Johnston, the senior assistant surgeon, and sixteen litter bearers, we went ahead with the line. We followed the artillery to its new location, and set up a flag on a suitable slope in its rear to designate a first-aid station. A brief drill was indulged in at this point to make sure that every man knew his position and the duties pertaining to it; also the canteens and equipments were given a final inspection.

When our skirmishers could be seen about the ruins of the blockhouse, we left the artillery behind and overtook the Second Wisconsin at the river.

At this time no shots were being fired on our side, but we could hear tremendous volleying to our left and in front. It was evident that the Sixteenth was getting into the fight and having more of it than we were.

We crossed the river by a disused roadway. The difficulty was considerable and the passage slow, because the descent to the stream was by a very steep and rocky passage that was, in reality, only the bed of a water course. Large, smooth rocks were inclined at an angle like a toboggan slide, and were placed one after another like steps in a stairway. At the bottom was an accumulation of rocks that had been loosened above and bowled down by tropic storms. It was necessary to dismount and help our horses in order to get them down.

The firing in the front continued for three quarters of an hour, and made our boys, who had not yet fired a shot, exceedingly eager to get up to where something was going on. While crossing the river we were overtaken by General Ernst and staff, with whom was Major Snowden, the chief surgeon of the brigade, who joined us. We learned from him that the Spaniards had blown up the bridge on the main road, and that the ambulances would not be able to cross. I sent back a message to Lieutenant Grannis, who was in charge of the train, instructing him to find a crossing and follow us into town as rapidly as possible. I had no idea that he could cross where we did.

On regaining the road on the other side of the river, we found it cut across at intervals by rifle pits, which were deserted, showing that the force defending the town had abandoned their job on our side, and were uniting against the Pennsylvanians at the other end.

Lieutenant Grannis brought his ambulances to the river at the point already described. Here he met the commander of the battery, who told him that he had explored the bank in both directions, but could find no crossing. The commander of the battery was in a quandary. There appeared to be only one thing to be done, and the doctor agreed to try it. One after the other the ambulances were sent bumping down the rocks, and by hard work and good management they were all landed successfully at the bottom.

The major then suggested various things that he would be willing to submit to, in this world and the next, if his guns could not follow anywhere that ambulances could go. He set to work with his men and accomplished an equally successful descent. Thus occurred the first and only illustration in history of an ambulance company leading a field battery in an action.

We of the advance detachment did not wait for this, but moved along with the advance of the line. Our men passed most of the companies of the Wisconsin regiment, which was proceeding rather cautiously.

We were just behind the leading company when we heard good United States cheering coming from over the housetops of Coama, and knowing that there was now no further need for caution, we struck spur into our horses and galloped through the streets ahead of everybody.

We found Company "C," the advance of the Sixteenth, on the bridge on the opposite side of the town, and beyond them the other companies coming in with a party of captured Spaniards, numbering nearly two hundred. The officers of the first company told us that they had left some wounded men behind, and directed us up the river. Following up the river for perhaps a quarter of a mile we found several parties of stragglers, but none of them could direct us to the wounded; they did not know of any.

We returned to the main road to obtain better directions, and arrived there in time to see the general come up and receive the report of the commander of the regiment. This time we obtained a guide, who conducted us across the river on foot and up a steep hillside, down which the Americans had been descending when they were fired on by the Spaniards, who were ambushed at the bottom along the roadway on the other side of the ravine.

We found two wounded men, each of whom was attended by several of his friends. There were also there the chaplain of the regiment, Captain Lowry, and Dr. Stearns, of the hospital corps, who with the aid of a private had been doing the work of an ambulance crew. When we reached the top of the hill we could see our

litter squads, which had followed on foot, at work searching the ground below.

Those of the wounded who were able to walk had been helped off the field by their comrades. Others were already being borne away by local Red Cross bearers. There was a local branch of this organization in every town we came to. As there were less than a dozen of our regiment wounded, and some had already been removed, our bearers cleaned up the field on their first visit, and then they spent the remainder of the day dressing the minor injuries of the Spaniards and natives, among whom there were about forty cases.

As soon as the wounded reached the road and were made ready for transportation, the ambulances appeared and were ready to receive them. Not a moment had been lost. If the affair had happened in New York city the recovery and care of the wounded would not have been more expeditiously or more carefully accomplished.

The Americans and Spaniards were treated alike in the ambulances and in the hospital; but the next morning, after another careful dressing, the Americans were loaded again into the ambulances and carried back to Ponce, twenty-two miles away, thence to the harbor and the hospital ship *Relief*; so that before their comrades had finished picking up the scattered equipments on the hillside the injured in the battle had their wounds fully attended to, and were actually on their way to the United States.

Another item of the work of the medical department that is not generally understood is that from the time a soldier falls on the fighting line, or becomes sick, until he is returned to duty, or until he is discharged for disability, or furloughed home, or dies, he is absolutely in the care of and under the military command of the surgeon. The surgeon finds shelter, eats, and clothing, makes up his accounts for pay, keeps his record, and in fact does everything for him that his company commander would do if he were well. He is transferred on paper by his captain to the hospital, just as he would be if the transfer were from one regiment to another, and he remains on the books of the medical department until he is transferred back again. It is this arrangement that makes possible the long-distance transportation of the wounded.

This triumph for the system of the medical department, just described, was duplicated three days later, when another engagement took place at Aguacate, about four miles above Coama, where the Spaniards were entrenched in force on a mountain commanding the road to Albionito. Our outposts had been fired on, and the field guns were sent up to cover the new tactical position.

After giving up all hope of seeing the shells and fumes of the fight, about half past five, we learned that we were not concerned further in the fighting, so the enemy became a dead weight on our backs, and we broke through and over the mountain, and down the whole

afternoon until our ammunition was out, when our crafty foes returned to life and treated us to further liberal volleys, which were sent after us as far as they would reach while we went back to camp. During both of these times our ambulances were very busy.

The roadway at this point wound by sharp turns up the mountain, and at every bend there was an exposed and a sheltered stretch. In the sheltered places the infantry supports rested, and here the ambulances found safe stations. Our men at the guns were well screened by being located between undulations in a field below the road. They could elevate their pieces and fire drop shots effectively, while the enemy, replying mostly with Mausers, which have a very flat trajectory, could only shoot over their heads. Their field guns were only two in number, and of a slightly smaller calibre than ours, but these caused most of the casualties.

But the battery with its horses and drivers had to cross the exposed places in the roadway in making changes of position, and the usual bad marksmanship of the Spaniards was not noticeable on these occasions. They had evidently measured their distances and prepared themselves very deliberately for maintaining their position.

The ambulances with their drivers and orderlies moved up and down across these same places without regard to volleys. One surgeon, Dr. Geddings, had his horse shot under him. It was impossible to see any difference, so far as courage is concerned, between the volunteers of the hospital corps and the regulars of the artillery. Both did their duty with the utmost precision, and the way in which an ambulance, sent back to the hospital with a load, would return and be again within the zone of danger, was enough to put the non-combatant soldier forever on a parity with his brother in the ranks.

That night the peace protocol was proclaimed, and the armies rested where they were, with little white flags on all the hilltops between them.

In his field report General Ernst said: "The ambulance service under command of Major James Johnston was prompt and efficient."

Thus ended the fighting and the rescuing of fighters in Puerto Rico, our little detachment of an ambulance company being the only portion of a great system that enjoyed the opportunity of showing what could be done under fire.

Aporetic Scarlet Fever. *Rénon (Giornale internazionale delle scienze mediche, December 15th)* communicated last year to the *Société médicale des hôpitaux* the case of a male child affected with scarlatina in whom the temperature did not rise beyond 99.2° F. Nevertheless, it was a case of scarlatina and not of scarlatiniform erythema of toxic or infective origin. As in analogous cases, there existed some proportional difference between the pulse and the temperature. The case resolved without complications.

INVERTED RETINAL IMAGES AND INVERSION OF THE FIELDS OF VISION.*

By JAMES L. MINOR, M. D.,
MEMPHIS, TENN.

In the *New York Medical Journal* of November 5, 1898, I reported a case under the head of Learning to See at Forty: first with One Eye, and later with Both. The man had been blind from birth, and at the age of forty acquired his sight through operations at my hands. I give in detail the tests to which he was subjected from the time he was allowed to use his eyes until the sense of sight was fairly well established.

Since the case was published I have received a few letters from physicians, in which not only an interest in the article was expressed, but a desire to know whether objects looked at and visual fields were inverted; for there are some physiologists who teach that we see things upside down, because inverted images of objects looked at are formed on the retina, and because the lower half of the retina is concerned in seeing things above the horizontal—the left half of the retina objects on the right side of the median line, etc.

They say that objects are seen, and appear to be, upside down, to infants and to others, when the function of vision is first exercised, and that only after the sense of touch has been so cultivated as to demonstrate that it gives the real and correct relation of objects do we have things seen appear to us in their natural position and relations—by a process called *reversion*. They say that without the sense of touch things would always appear upside down through the sense of sight, and that if a person possessed of the sense of touch, but not with nor ever having had that of sight, be made to see, objects seen would appear upside down, until by cultivation this process of reversion established the proper relation between the senses of touch and vision. My patient was in this latter condition, and it was supposed that his experiences would throw some light upon this subject—one alike perplexing to the teacher and a stumbling-block to the student. There was neither inversion of object nor of field of vision with him.

The first object he saw with distinctive shape was correctly appreciated (a glass goblet, the outlines of which he mapped out by movements of the hand before touching). And the first object he saw—a round ball—he reached out and touched with little hesitation, though it was two feet off and about 45° below the level of his eyes, and the upper half of the retina was concerned in getting his first glance of it.

It seems to me that this is as it should have been, for the sense of direction of an irritant is the same for the retina that it is for any other nerve of the body; it is referred back to the same direction whence it came,

* Read before the Tri-State Medical Association, at Memphis, Tenn., December 24, 1898.

opposite the point of impact. For instance, if the fingers be extended and the hand held palm upward, and any part of the palm or palmar surface of the fingers be irritated, the force producing it will be recognized as having come from above; or, if the palm be down, the force will have come up, etc.

Now, if the fingers be curved up somewhat on the palm, so as to make a sort of cuplike cavity, the concavity of which will be the palmar surface of the hand and fingers, the forearm being vertical, the wrist bent back, so as to direct the concavity forward, we will have a palmar surface arranged on the plan of the retina.

The lower half of the cavity facing upward will be the palm of the hand, irritation of which must come from above; the upper half of the cavity, the palmar surface of the fingers facing downward, irritation of which must come from below. The retina is just such a cup-shaped nervous expansion, with its perceptive elements facing the concave surface, and it is as natural that objects in the field of vision should excite correspondingly opposite portions of the retina as it is necessary for the inverted image of an object to be formed on that part of the concavity of the retina perceiving it.

An error has been fallen into in confounding the inverted image of the object formed on the retina—a simple phenomenon of refraction, which may be visible to the observer but not to the subject—with the recognition of the object by the brain, and its projection to its proper position in space. And the so-called reversion of the field of vision—as compared with the sense of touch—differs in no material way from nerve action elsewhere. The fact that my patient had perception of light before he was operated upon may be cited as a possible explanation of his correct interpretation of the field of vision, but the explanation which I have given of retinal perception and projection makes such inference unnecessary.

COMBINATIONS OF SYNERGISTS IN REDUCED DOSES.

By B. SCHEINKMAN, M.D.

As the result of considerable and careful observation I find that the method of combining therapeutically analogous drugs in practically minute doses, so as to constitute in the aggregate a moderate therapeutic dose, is by far superior in effect to a similar dose of any individual one of its constituents administered alone. Especially is this true with the members of the coal tar and urea and with most of the alkaloids. It seems a truism when in combination, while their respective characteristic therapeutic properties are acting conjointly in perfect harmony, their toxic properties—and such are, as a rule, possessed by nearly all of them, though there are

not usually analogous in character—are either individually too insignificant, being in small doses, or they neutralize one another more or less effectively. Thus, for example, we are all well familiar with the depressing effects upon the heart and circulation frequently observed after even moderate therapeutic doses of antipyrine, phenacetine, antifibrine, etc., as well as with the more or less severe symptoms following a moderate dose of quinine or caffeine, to say nothing of their occasional uncertainty in action. We also know of the almost absolute uselessness or inactivity of the above-mentioned drugs as therapeutic agents when administered individually in minute doses; while, on the other hand, by combining these drugs in practically very small doses, so as to constitute in their aggregate a moderate dose, I find that their respective individual characteristics are greatly modified and an almost new therapeutic action is produced, which, while being more powerful and more certain in its therapeutic effects, is completely lacking in any of the toxic properties possessed by any one of its constituents. The following prescription as a type will illustrate a combination which I have been in the habit of giving for a number of years with the most gratifying and happy results for antipyretic, analgetic, antiperiodic, and antiseptic purposes, results so striking and so positive as to lead me to the conclusion that it is the most excellent, the most harmless, and the most certain method of administration of these drugs for the above-mentioned purposes; reducing temperature and alleviating pain much more readily, more certainly, and more safely, than any one of them individually, and above all being entirely free from the unpleasant symptoms frequently following a similar dose of any individual one of them. The following is recommended as the dose for an adult:

R Antipyrine,	} of each ½ drachm;
Phenacetine,	
Quinine sulphate,	
Powdered ginger,	
Caffeine citrate	15 grains.

M. Divide into fifteen capsules.

S.: One every two hours.

In the case of children a proportionate dose is given in a mixture, the vehicle being equal parts of syrup of verba santa and chlor glycyrrhizæ, a composition which disguises effectively the latter taste.

As can be readily seen from the foregoing prescription, the ingredients, although employed individually in very small doses, are yet wonderfully effective in their conjoint cooperative action toward the reduction of temperature and; while their toxic properties, on the other hand, are both so infinitesimal that they do not affect one another. In combining these drugs, therefore, we evidently obtain their purely beneficial or desirable effects minus their objectionable or deleterious properties, and hence the advantages I am attributing to this method over others.

Another point of importance which I am sufficiently warranted in alleging for the above combination particularly, is that it possesses decided prophylactic power against many diseases of microbic origin, especially against the streptococcus. I am supported in this view by numerous cases, in which this combination has acted prophylactically, where sepsis would appear to have been inevitable, and by having adopted the rule of administering the above combination in almost every puerperal case, whether at term or premature. I have been so fortunate as never to encounter a case of sepsis in spite of a course of almost ten years of active obstetrical practice under exceedingly unfavorable conditions and surroundings, or rather under conditions highly favorable to the production of sepsis. Neither have I ever observed the slightest injurious effects or unpleasantness to the patient from its administration.

With about the same gratifying results I have made use of this combination in a number of other affections characterized by pyrexia and neuralgia, such as acute articular and muscular rheumatism, acute pneumonia, erysipelas, and malarial affections, also in typhoid fever, although with less marked benefit in that disease.

The method of administering drugs in combination is by no means new, nor do I claim any originality or priority for the particular combination alluded to, since for the main part of it I am greatly indebted to one of my learned and highly esteemed teachers, Dr. W. H. Thomson, who has always been one of the most ardent advocates of combining similar drugs with a like purpose. What I do state, however, is the fact that so far as I have observed, the method, excellent as it is, is very seldom, if at all, practised by the profession in the manner and with the object above described. This method must not, however, be confounded with the so-called "dosimetric system," the main feature of which is the administration of individual drugs, separately or conjointly, in exceedingly minute doses at very short intervals, with the object of impressing the system with their cumulative effects. This object is entirely different from the one to which I am alluding.

An incident which has lately occurred to me is well illustrative of the unpopularity of this method of treatment with the modern physician. A case that had been diagnosed as acute articular rheumatism was treated by several physicians, including myself (the patient being my sister), in the usual routine way with the salicylates, etc., but unfortunately without the slightest effect on either the temperature or the pain. On one occasion, when the patient complained to me bitterly of feeling much worse under the treatment, and on finding her temperature and other symptoms persisting in spite of the routine course, I decided upon my favorite prescription, in the absence of my colleague, who could not be found at the time. On his arrival, however, somewhat later, and on learning of my prescription, which was as yet at the druggist's, he manifested surprise at

its ridiculousness; in fact, his surprise was so great that after a preliminary conference with the druggist, they both came to the final conclusion "that the poor fellow [the author of the prescription] must have become either mentally unbalanced or be the victim of gross professional ignorance"; and having strongly forbidden the patient to take the medicine, my friend assumed the attitude, as I was informed, of having been "in time to save the patient's life." Considering the great popularity these drugs have always enjoyed as antirheumatics by the profession at large, and also the opinions expressed by such prominent men as Sée, Dujardin-Beaumez, Fraenkel, and others, who have claimed for antipyrine and phenacetine a place not only as specifics in acute articular rheumatism, but also as preventives of the heart complications so common in this affection, and which popularity could hardly escape the notice of a modern physician, it appears to me that it is not the drugs *per se* so much as the combination of these drugs in small doses that puzzled and alarmed my friends.

As to the *modus operandi* of this combination *versus* other methods, my belief is based upon the following common-sense theory. Rise of temperature, pain, cough, irritability, etc., are symptoms certainly indicative of some abnormal condition or process somewhere in the economy, otherwise the symptoms would have to be regarded as normal physiological phenomena, and as consequently requiring no treatment. Hence, in speaking of functional affections causing any one of the above symptoms, we must necessarily admit that the term "functional" is being used in a comparative sense only, either to denote our ignorance as to the distinct pathology of a given affection and in contradistinction to affections of known pathology, or that the morbid condition is of a slight and easily removable nature. Taking, for instance, trigeminal neuralgia as illustrative of a type of functional affections, and granting it a fair and intelligent consideration, we shall soon come to the conclusion that there is something morbid or abnormal going on either in the immediate neighborhood or remote from it, which gives rise to this local disturbance; that at least there is some cause productive of these symptoms; for it must be borne in mind that a symptom must be either the result of an irritation upon the nervous system produced by some pathological process, or the means and efforts that are employed by Nature to rid itself of a morbid process or condition by increased cellular activity or metamorphosis, brought about by such morbid condition acting as an irritant upon the vasomotor system or other nerves, and giving rise to either motor, vasomotor, or sensory disturbances. Hence it clearly follows that anything which would check or alleviate a symptom could only do so by either paralyzing or suspending the physiological sensibility and conductivity of the nervous system, while allowing the morbid process to go on doing its mischief, as would be the case with an anæsthetic, or by checking, or at least con-

teracting in some manner the morbid process itself that is giving rise to the symptoms so as either to check or to counteract its virulence, and consequently to act as an organic medicine. Therefore, in speaking of an analgetic, anodyne, sedative, etc., we merely express by it our ignorance of its real nature, and the term is in this regard also closely related to the term "functional."

It is therefore obvious that any remedial agent which, being not an anesthetic, is yet reputed to possess analgetic, anodyne, or antipyretic properties, should necessarily be regarded as a real curative, or, as we sometimes call it, organic remedy in any affection, whether organic or functional, or, in other words, whether of known or unknown pathogeny.

It should be borne in mind, however, that by curative is not necessarily implied also reparative, for in the majority of instances the checking of the process alone suffices to effect a cure, leaving to Nature the repair of the already existing lesions.

Although, as previously remarked, some symptoms, such as fever, cough, diarrhœa, vomiting, etc., are often the means used by Nature to rid herself of a certain morbid condition or process, and consequently by checking such symptoms we are in danger of depriving Nature of her means of defense, which would appear to be highly detrimental to our purpose unless we attack the disease itself, we are also, fortunately for my theory, well aware of the fact that the means thus used by Nature are often not only incorrect and inefficient, but very frequently more destructive in character than the original disease. Consequently, we are frequently called upon to guide and correct Nature in her efforts, so that in checking any such symptom by any appropriate remedial agent, with very rare exceptions only good results and no harm should ensue, inasmuch as we are counteracting harmful symptoms. In cases, however, where harm is discovered to arise from such interference with a given symptom, as sometimes happens, I am convinced that in the majority of these cases the harm will be found to be due, not to the counteraction of the symptoms, but to the given agent, which, as already said, usually possesses also properties other than its therapeutic ones, and which, when given in a sufficient dose for its therapeutic effects, exercises at the same time also its full deleterious influences in other directions, frequently necessitating its entire discontinuance.

We may instance the case of antipyrine, which, when administered in its antipyretic doses in fevers from any cause, we are frequently obliged to discontinue, owing to its well-known depressing effect upon the heart and other unpleasant symptoms, but certainly not on account of its antipyretic effect having done any harm, in having counteracted or possibly deprived Nature of its means of defense. Indeed, I have never seen an instance where an effective antipyretic has done anything but good in pyrexia from any cause, save from other harmful or toxic properties possessed by nearly all of these agents which

exert also simultaneously with their antipyretic effects toxic influences in other directions, thus rendering them often unfit for our purpose. The combination method offers itself as an excellent expedient in disposing of these difficulties; for, by combining several of them possessing analogous antipyretic properties in small doses, we obtain the conjoint benefit of their pure antipyretic effect alone, their toxic properties being either individually too insignificant, or mutually counteracting, as can be seen from the above prescription. They thus doubtlessly exercise a curative action upon the disease itself, or at least effectively antagonize symptoms which in the majority of cases play the main rôle in the disease, and are very often the direct cause of death. In fact, death is seldom due directly to the disease *per se*, but rather to the immediate effects of the symptoms, before the disease has done any serious mischief. Indeed, we may quite humorously, though often very truly, express ourselves, that the majority of our deaths are only functional in character, or that "there is nothing serious in X's death; it is only due to shock or to some functional heart failure as a result of a certain irritation upon the vagus or cardiac ganglia." Hence the checking or counteracting of symptoms effectively by any remedial agent, I consider not only always indicated and beneficial, but frequently even life-saving, regardless of the pathological conditions which may be at the bottom of them, provided we eliminate the toxic effects simultaneously produced by the same agents; and the only way to accomplish this end is, as it seems to me, by the combination method.

As regards symptoms which are considered essential and do prove efficient in the efforts of Nature to resist or eliminate disease, and in which interference would prove injurious indeed—*e.g.*, in the case of vomiting caused by the irritation of the stomach due to some corrosive or offending material ingested, or a cough due to excessive exudation into the bronchial tubes, or a foreign body in the trachea and the like, I do not consider it necessary to say that the physician is intelligent enough to allow Nature full play in her efforts and means to help herself.

AN OPEN SAFETY PIN LODGED IN THE CARDIAC END OF THE STOMACH FOR SEVEN DAYS.

ITS SUCCESSFUL REMOVAL BY GASTROTOMY

BY WILLIAM PETRY, M. D.

RESIDENT PHYSICIAN AT THE HOSPITAL OF ST. BARBARA, NEWARK, N. J.

Mrs. S., aged thirty-three years, while attending to the nursing of her infant during the night of November 29, 1898, placed an open safety pin, several at over an inch in length, in her mouth, and awoke the following morning with a feeling of soreness in her throat, extending down to a point opposite the xiphoid or costo-sternal junction. She concluded that the pin had swallowed the pin and promptly took an emetic, which emptied her stomach but failed to remove the apparent cause of trouble.

The pain behind the right sternal border increased

in severity, and there being some doubt about her having swallowed the pin, she was treated for several days by her family physician, Dr. Gaston, of Somerville, N. J.

Four days after the accident had occurred, during which time the patient was unable to swallow any solids, and very little liquid food, the doctor brought the patient to Dr. Edward J. Ill, of this city, who began search for the pin by the following ingenious method, which in this case proved highly satisfactory and again demonstrated the possibility of locating foreign objects in the human body without the aid of the Röntgen rays. The tip of an ordinary œsophageal bougie was coated with wax, and the instrument passed into the stomach, contact with the teeth being carefully avoided. The point on the bougie opposite the incisor teeth, after the instrument had been fully inserted, was marked. After withdrawing the bougie a distinct scratch was detected on the wax covering, the upper extremity of the scratch being fourteen inches and a half below the point on the bougie above noted—in other words, the normal distance between the teeth and the cardiac orifice. This proved the location of a foreign body at or near the cardiac orifice. The experiment was repeated on three successive days with the same result.

The patient was prepared for gastrotony. The intestinal tract was thoroughly emptied by repeated doses of calomel, and no food allowed by mouth during the twenty-four hours preceding the time set for operation. During the night preceding operation, however, the patient was given in divided doses one quart of warm water, in which one teaspoonful of sodium bicarbonate had been dissolved. On December 5, 1898, seven days after the accident, the abdomen was opened by a median incision in the epigastrium, the stomach was drawn into the wound and opened by a transverse incision halfway between the lesser and greater curvatures. An attempt to locate the pin by means of the index finger failed; the stomach wound was increased to nine cubic centimetres in length, so that the whole hand could be inserted, after which the pin was found just above the cardiac orifice, the point of the pin being directed downward.

The operator, Dr. Ill, found that, contrary to the teachings of anatomists, the opening of the œsophagus into the stomach in this case was to the right of the spinal column and aorta, which accounted for the impossibility of reaching the orifice by the index finger. The pin was grasped near its rounded end with long artery forceps, reversed, while the finger covered its point, and easily removed. The wound in the stomach was closed by a double row of interrupted silk Lembert sutures and the abdomen closed without drainage. For five days after the operation the patient was nourished by enemata, and made an uncomplicated recovery without the slightest symptom of inflammation or gastric irritation.

So far as the writer of this is aware, but two cases of removal of foreign bodies from the lower end of the œsophagus by gastrotony have been reported, the first by Dr. M. H. Richardson in the *Lancet*, October 8, 1887, and the second by Dr. W. T. Bull in the *New York Medical Journal*, October 29, 1887. The present case is, therefore, sufficiently uncommon to justify its publication. Prof. or Howard A. Kelly has taught the use of the wax covered urethral bougie in the search for renal calculus. Dr. Ill has carried out a similar idea in the above case with absolute certainty of detecting and locating the foreign body. It must always be borne in

mind that the cardiac orifice is fourteen inches and a half below the incisor teeth in the vast majority of adults.

The woman evidently swallowed the pin with the rounded or spring end first, but before reaching the stomach it was reversed by the effort of vomiting, and its point became lodged in the cardiac end of the stomach.

It is apparent that the stomach tolerates so large a wound as nine cubic centimetres in length very well.

In connection with this case it is interesting to note the displacement of cardiac orifices to the right instead of left of aorta, as described in the books. It was far to the right of the spine, and the introduction of the entire hand was necessary to locate it. This displacement explained the location of pain behind the right sternal border.

Therapeutical Notes.

An Enema for Urticaria.—In the *Clinica moderna* for December 21st we find the statement that in severe cases of urticaria benefit has been found to follow the use, four or five times a day, of an enema having the following composition:

℞ Sodium bicarbonate 300 grains;
Laudanum 30 drops;
Boiled water 7,500 grains.

M. As improvement takes place, the amount of sodium bicarbonate may be reduced gradually to seventy-five grains.

Pastilles for Fœtid Breath.—The *Journal de médecine de Paris* gives the following:

℞ Powdered coffee 675 grains;
Vegetable charcoal 225 "
Powdered sugar 225 "
Vanilla 225 "
Mucilage of Senegal gum q. s.

M.

Make into pastilles, each containing fifteen grains. Five or six may be taken daily.

Iodine in the Treatment of Infantile Gastro-enteritis.—Bizine (*Semaine médicale; Revue des maladies de l'enfance*, January) reports particularly favorable results from the use of this mixture:

℞ Emulsion of castor oil 6 ounces;
Oil of peppermint 3 drops;
Oil of cloves 5 "
Tincture of iodine 10 "
Chloroform 2 "

M. S.: A teaspoonful every hour. The mixture should be kept on ice, to prevent decomposition. One bottle is usually enough, but if after that has been taken there is still a little diarrhoea, ten grains of iodized starch may be divided into six doses, one to be taken twice a day.

An Ointment for Chapped Hands.—The *Journal des praticiens* for December 31st credits the following formula to Comby:

℞ Menthol 1 part;
Salol 2 parts;
Olive oil 10 "
Lanolin 30 "

NEW YORK, SATURDAY, FEBRUARY 18, 1899.

TEMPORARY GLYCOSURIA AND ALBUMINURIA FROM
THE LIFE-INSURANCE POINT OF VIEW.

MUCH has been written upon this subject, but we do not remember to have seen a better presentation of it of late than is to be found in the December number of the *American Practitioner and News*, in the report of a meeting of the Louisville Medico-chirurgical Society. Transitory glycosuria was the subject formally under discussion, but temporary albuminuria also was considered. A report presented by Dr. Dabney reminded Dr. Cecil of the case of a short, fat, and rather florid woman, forty-seven years old, whom in an examination for life insurance he had found perfectly healthy, save for her urine containing a small amount of sugar, estimated roughly at one third of one per cent. The amount of urine was not increased and its specific gravity was only 1.019. There was neither the thirst nor the appetite of diabetes, and the speaker, thinking the glycosuria might be transitory, suggested that her application be held in abeyance. A second examination, made some days later, showed that there was still sugar in the urine. Dr. Anderson cited some arguments that he had shortly before heard brought forward by Dr. Ochterlony to the effect that one could not make a diagnosis of diabetes simply by the presence of sugar in the urine; there must be some other manifestation, such as thirst, polyuria, or emaciation. The same was true of albuminuria as a sign of kidney disease.

Dr. Bailey, an examiner for life insurance, stated that he could not ask any company that he represented to insure a person whose urine showed either albumin or sugar. While it was recognized, he said, that albuminuria or glycosuria might be transitory, he asked how one could know that in a given case it was transitory, unless repeated examinations were made and the abnormal condition was found only once. Almost any healthy person, he remarked, might show albumin in the urine after an unusual amount of bicycle riding, yet even in such cases it was sometimes very difficult to decide whether the albuminuria was transitory or not, and in the case of a man with such a history he would not ask a company to accept the risk. He did not feel free to recommend a person for insurance if at the time of

the examination the urine contained either albumin or sugar, no matter what the circumstances were. The best that he could bring himself to do was to ask that the application be "held up." We take it that this is the view taken by the great majority of capable and conscientious examiners and by the conservative companies also.

THE EVIL OF CLUB PRACTICE.

If we are to escape in this country such a growth of club practice as afflicts our professional brethren in certain European communities, decided steps must be taken before that particularly despicable form of the practice of medicine has taken root, as it is sure to do if we content ourselves much longer with the "expectant treatment." We are rejoiced to see, therefore, that at least one influential medical organization has taken the matter in hand in a way that promises to do much toward strangling the evil.

We have in mind certain action that was recently taken by the Syracuse Academy of Medicine. On December 1st a proposition signed by thirty-three members was laid before the academy. The purport of it was to amend the constitution by so changing one of its sections that it should read as follows: "This academy shall be composed of resident and non-resident fellows who are regular practitioners of medicine and who have been in active practice for at least two years and who agree not to engage, by written or verbal contract, to attend medically or surgically by the year, by the month, or for any specified time, the members of any lodge, club, sick-benefit society, or insurance society, or the employees of any contractor or commercial house, at so much *per capita* or for any specified sum. This shall not be construed to mean the care by contract of any ward or convict of the city, county, or State;" also by adding the following section to the by-laws: "Any fellow who violates any of the provisions of Section 1, Article II, of the constitution [the one proposed to be amended] shall be heard by the council in his own behalf after charges have been preferred, and if such charges are sustained he shall be expelled." Recently, after the necessary formalities, these proposed changes were adopted almost unanimously.

If there are but one hundred at Syracuse competent practitioners, would it not be better to have a club practice, and we are confident that such an action would not have been necessary if the majority of their brethren in the State had taken the Syracuse Academy of Medicine as a model, and had endeavored to carry with them the same principles of association with the

community and lead them to mend their ways. It ought also to deter younger men who might otherwise be led astray. If it has these results in Syracuse, it would no doubt have them elsewhere, and we hope that the academy's example will be followed widely. The evil of club practice must be eradicated.

MINOR PARAGRAPHS.

"EMBALMED" BEEF.

ANOTHER yellow-journal bubble seems to have collapsed. An investigating board, one thoroughly desirous of getting at the facts, has come to the conclusion that there was nothing about the canned beef furnished to the army during the late war to justify its being called "embalmed." Soldiers will have their jokes, however, and probably some of the beef was not inviting. We believe that this was due to some imperfection in canning that may yet be discovered and in the future avoided. The purveyors were in no way to blame.

MILITARY DOCTORS.

THE *British Medical Journal* for January 21st cites Lord Wolseley as having said more than once that medical officers are not soldiers, and mentions the case of General J. Frédéric Canonge, now commanding the fifteenth French army corps at Marseilles, as an instance to the contrary, he having received his M. D. degree on the same day that he was promoted to the "combatant" rank of a lieutenant. The motto of his thesis, "*Miles sum, militis nihil a me alienum puto*," was felicitous. We congratulate France on possessing such an excellent example of the fact that a medical officer may be a good soldier; but with General Leonard Wood, M. D., in view we can do so without inordinate envy.

INDIRECT ATAVISM IN THE TRANSMISSION OF TUBERCULOSIS.

WEBER, in an article on The Heredity of Tuberculosis (*Journal des praticiens*, January 21st), cites a case reported by Boungies as an example of "oblique heredity," which seems to be the same thing as Sedgwick's indirect atavism. A young girl was seduced and gave birth to a child. Both the child and its father soon died of tuberculous disease. Then the girl, herself strong and healthy, married a healthy and vigorous man. Four children were born to them. The first, second, and third died of tuberculous meningitis. The fourth, a girl, was born healthy, grew up, and married a healthy man. All the children that she bore were affected with tuberculous glands.

A CASE OF MALTA FEVER IN PHILADELPHIA.

In the *Proceedings of the Pathological Society of Philadelphia* for February 1st Dr. J. H. Musser and Dr. J. Sailer report the case of an army officer who appears to have contracted the disease in Puerto Rico. Malarial plasmodia were frequently sought for in his blood, but never found. A culture of the *Micrococcus melitensis* gave an agglutimative reaction with the patient's blood. The author intimates that the name of *febris undulans*, suggested by Hachez, is the most appropriate for Malta

fever, which, they remark, occurs in Malta, in Naples, at Gibraltar, on the northern coast of Africa, in India, and possibly in Hongkong and along the Danube. So far as they know, it has not before been observed in the United States.

HÆMORRHAGE FROM ŒSOPHAGEAL VARICES IN LATENT CIRRHOSIS OF THE LIVER.

At a recent meeting of the Paris *Société anatomique* (*Gazette hebdomadaire de médecine et de chirurgie*, January 26th) Marmasse showed the liver and the œsophagus of a man who had had hæmatemesis without presenting at the time any sign of cirrhosis. Subsequently, however, cirrhosis of the liver was recognizable clinically. After his death three varicose swellings were found in the lower portion of his œsophagus, and there was an erosion, plugged with a clot, at the summit of each dilated venule.

THE REGULATION OF THE SALE OF POISONS IN ILLINOIS.

On January 31st Mr. Kettering introduced into the lower house of the Illinois legislature a bill to regulate and restrict the sale of compounds or preparations of drugs or chemicals which may be poisonous or deleterious to health. The bill seems to us rather exacting in some respects, but its general features appear to be wholesome.

THE COLORADO MEDICAL JOURNAL.

We wish to congratulate our esteemed Denver contemporary on the improved appearance of its January number. The improvement is not one of appearance only; the *Journal* contains more matter than before, and the quality of its contents is excellent.

ITEMS.

The New York Academy of Medicine.—At the last stated meeting, on Thursday evening, the 16th inst., Dr. Herman M. Biggs read a paper on The Serum Treatment and its Results, which was discussed by Dr. Henry Koplik, Dr. L. Emmett Holt, Dr. W. H. Park, Dr. J. Winters Braman, Dr. A. Lambert, and Dr. W. R. Pryor.

At the next meeting of the Section in Ophthalmology and Otology, on Monday evening, the 20th inst., the following cases will be presented: Purulent cystitis and pemphigus of the conjunctiva, by Dr. H. Knapp; partial atrophy of the optic nerves due to hæmorrhage from the uterus, by Dr. John E. Weeks; the final result of plastic operations for epithelioma of the inner canthus, and the result of operation for symblepharon, by Dr. J. H. Claiborne. Dr. Ward A. Holden will read a paper on the Pathology of the Amblyopia following Excessive Hæmorrhage, and of that following the Ingestion of Wood Alcohol as determined experimentally.

At the next meeting of the Section in Medicine, on Tuesday evening, the 21st inst., the following papers will be presented for discussion: Hydrophobia and its Preventive Treatment; an Analysis of Some Cases, by Dr. Pollen Cahot; and Cases of Hydrophobia in Animals, by Dr. S. K. Johnson and Dr. H. D. Gill.

At the next meeting of the Section in Laryngology and Rhinology, on Wednesday evening, the 22d inst., Dr. Jonathan Wright will read a paper entitled Remarks on the Etiology of Nasal Polypi, which is to be

discussed by Dr. Henry L. Swain, of New Haven, and Dr. J. E. Newcomb. There will be a continuation of the discussion on Dr. Freudenthal's paper on the Treatment of Dysphagia and Cough, especially in Tuberculosis. Cases will be reported by Dr. Joseph W. Gleitsmann.

At the next meeting of the Section in Obstetrics and Gynaecology, on Thursday evening, the 23d inst., the following papers will be presented for discussion: A Report of a Case treated by Unusually Large Saline Infusion, by Dr. J. Riddle Goffe; and Puerperal Infection, by Dr. Julius Rosenberg. Specimens and instruments will be exhibited.

At the next meeting of the Section in Neurology and Psychiatry, on Friday evening, the 24th inst., the following papers will be read: The Pathology of Paralysis Agitans, by Dr. Charles L. Dana; and Tetanoid Seizures in Epilepsy, by Dr. L. Pierce Clark.

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, and cholera were reported to the supervising surgeon-general of the United States Marine-Hospital Service for the week ending February 11, 1899:

Small pox—United States.

San Francisco, Cal.,	Jan. 31,	2 cases; one a railroad employee from Colorado, one a leper in pest house.
Denver, Col.,	Jan. 7-14,	1 case.
Washington, D. C.,	Jan. 31,	2 cases.
Indianapolis, Ind.,	Jan. 21,	4 "
Louisville, Ky.,	Dec. 20-Feb. 8,	47 "
Detroit, Mich.,	Jan. 21-Feb. 1,	7 "
Omaha, Neb.,	Jan. 22-28,	3 "
New York, N. Y.,	Jan. 28-Feb. 4,	1 case.
Cincinnati, Ohio,	Jan. 21-Feb. 3,	49 cases.
Cleveland, Ohio,	Jan. 21-28,	1 case.
On steam-ship <i>Taconon</i> at Louisville, Ky.,	Jan. 20,	3 cases.

Small pox—Foreign.

Buenos Ayres, Argentina,	Nov. 1-20,	5 deaths.
Bahia, Brazil,	Dec. 17-Jan. 7,	56 cases, 6 "
Rio de Janeiro, Brazil,	Dec. 16-23,	21 "
London, England,	Jan. 7-14,	1 case.
Mexico City, Mexico,	Jan. 22-29,	5 cases, 3 "
Monterrey, Mexico,	Dec. 29-Jan. 5,	2 "
Moscow, Russia,	Jan. 7-14,	3 "
Odessa, Russia,	Jan. 7-14,	1 death.
St. Petersburg, Russia,	Jan. 1-14,	7 "

Yellow Fever.

Bahia, Brazil,	Dec. 21-Jan. 7,	2 cases, 1 death.
Rio de Janeiro, Brazil,	Dec. 16-24,	7 "
Chihuahua, Mexico,	Jan. 22-28,	2 "

Cholera.

Calcutta, India,	Dec. 17-21,	21 deaths.
Madras, India,	Dec. 10-16,	6 "

The Southeast Kansas Medical Society.—The quarterly meeting will be held in Fort Scott, on Tuesday, March 7th, under the presidency of Dr. P. W. Ramey, of Oswego. The programme contains the following titles: Pneumonia, by Dr. M. Coryell, of Cairo; Diphtheria in a Liberator of the Corns, by Dr. E. B. Telford, of Kansas City; Cystitis, by Dr. J. B. Carver, of Fort Scott; Rectal Fistula, by Dr. George E. Cole, of Girard; Diphtheria, by Dr. L. R. Sellers, of Fort Scott; Post-nasal Catarrh, by Dr. M. E. Jarrett, of Fort Scott; Injuries of the Elbow Joint, by Dr. J. W. Parsons, of Litchfield; Disease of the Gall Bladder, by Dr. J. L. Jewell, of Moran; Disease of the Rectum, by Dr. J. B. Anderson, of Chetopa; Pharynx, by Dr. C. S. Benson, of Barthol; Compunctivitis, by Dr. A. C. Granger, of Pittsburgh; Granular Compunctivitis, by Dr. J. W. Parsons, of Parsons; Gonorrhoea, by Dr. George S. Liggett, of Oswego; and Moral Therapeutics, by the Rev. J. J. Purcell, of Parsons.

The Illinois State Board of Health.—At the last election, held on January 17th, the following-named physicians were elected officers and members for 1899: Dr. C. B. Johnson, of Champaign, president; Dr. R. F. Bennett, of Litchfield, treasurer; Dr. J. A. Egan, of Springfield, secretary and executive officer. Dr. J. C. Sullivan, of Cairo; Dr. L. Adelsberger, of Waterloo; Dr. Florence W. Hunt, of Chicago; Dr. P. H. Wessel, of Moline; and Dr. M. Meyerovitz, of Chicago.

A New Obstetrical Journal.—*Obstetrics* is the title of a new monthly of sixty pages edited by Dr. Edward A. Ayers and published in New York. The first number, for January, 1899, has a handsome appearance.

A New Central American Medical Journal.—We have received the first number of the *Boletín de la Sociedad de Medicina y Cirugía de Panamá*, a monthly periodical of eighteen pages, edited by Dr. Julio Qeaza and Dr. José E. Calvo.

A New Kansas Monthly.—Dr. William E. McVey, formerly of the *Kansas Medical Journal*, the publication of which has been discontinued, has brought out the first number of the *Medical Monograph*, a monthly of about one hundred and fifty pages. It is notable for the fact that all but one of its original articles, nine in number, relate to diseases of the liver. We infer that the policy of grouping articles in this manner is to be a distinctive feature of the new journal. It is published in Topeka.

The Society of Medical Jurisprudence.—The special order for the meeting of Tuesday evening, February 14th, was a paper on The Medical and Legal Aspects of Hysteria Induced by Injury, by Dr. Pearce Bailey.

The St. Louis Medical Society.—At the last regular meeting, on Saturday evening, the 11th inst., Dr. G. Wiley Broome presented a Preliminary Report on the Effects of Ligating the Dorsal Vein of the Penis for Functional Impotence.

The New York State Medical Association.—The Fifth District Branch will hold its fifteenth annual meeting in Brooklyn on Tuesday, May 23d, under the presidency of Dr. J. D. Bryant.

Changes of Address.—Dr. R. N. Hawley, to No. 84 West One Hundred and Fiftieth Street; Dr. James P. Warshaw, to No. 68 Greene Avenue, Brooklyn; Dr. J. V. D. Young, to No. 60 West Seventy-sixth Street.

Marine-Hospital Service.—*On the Establishment of Stations and Public Health Service on the Atlantic Coast, with a Commission to the United States Marine-Hospital Service for the Purpose of Investigating the Diseases of the Coast.* By BENJAMIN C. F. SHAW. To be published by the Government Printing Office, Washington, D. C., in 1899.

BRUNNER, W. F., Surgeon, U. S. Marine-Hospital Service, at Manila, P. I., has been ordered to inspect the city of Manila, P. I., from Jan. 27, 1899.

COBB, J. O., Passed Assistant Surgeon. To report at bureau for special temporary duty. February 2, 1899.

COMFORT, N. C., Junior Hospital Steward. To report to acting assistant surgeon in temporary charge, Cincinnati, Ohio, for duty and assignment to quarters. February 8, 1899.

CUMMING, H. S., Assistant Surgeon. To proceed to Alexandria, Va., for special temporary duty. January 27, 1899.

DAVIS, HENRY E., Junior Hospital Steward. To report to medical officer in command, Boston, Massachusetts, for duty and assignment to quarters. February 8, 1899.

EAGER, J. M., Passed Assistant Surgeon. To proceed to Alexandria, Va., for special temporary duty. January 28, 1899.

GAHN, HENRY, Steward and Chemist. To proceed to New York, N. Y., for special temporary duty. February 1, 1899.

GLENNAN, A. H., Surgeon. Detailed by the secretary as quarantine officer, port of San Juan, Porto Rico, in accordance with executive order dated January 20, 1899. February 1, 1899.

GOODMAN, F. S., Senior Hospital Steward. To proceed to Havana, Cuba, for duty. February 1, 1899.

GREENE, JOSEPH B., Assistant Surgeon. To proceed to San Francisco, Cal., and report to the medical officer in command for duty. January 27, 1899.

GUTIÉRAS, G. M., Passed Assistant Surgeon. Granted leave of absence for ten days. February 3, 1899.

LAVINDER, C. H., Assistant Surgeon. To proceed to San Juan, Porto Rico, and report to Surgeon Glennan for assignment to duty at Ponce, Porto Rico. January 31, 1899. Detailed by the secretary as quarantine officer, port of Ponce, Porto Rico, in accordance with executive order, dated January 20, 1899. February 1, 1899.

PETTUS, W. J., Passed Assistant Surgeon. To proceed to Norfolk and Portsmouth, Va., for special temporary duty. January 28, 1899.

PURVANCE, GEORGE, Surgeon. Granted leave of absence for ten days. February 7, 1899.

ROSENAU, M. J., Passed Assistant Surgeon. To proceed to Alexandria, Va., for special temporary duty. January 27, 1899. To proceed to Santiago, Cuba, as inspector. January 31, 1899. Detailed by the secretary to organize quarantine service at port of Santiago, Cuba, in accordance with executive order dated January 20, 1899. February 1, 1899.

ROSENAU, M. J., Passed Assistant Surgeon. To proceed to New York city for special temporary duty. February 2, 1899.

WERTENBAKER, C. P., Passed Assistant Surgeon. To report to Governor Chandler at Atlanta, Ga., for special temporary duty. January 27, 1899.

WHITE, M. J., Assistant Surgeon. To proceed to Philadelphia, Pa., for duty. January 31, 1899.

WHITE, J. H., Surgeon. To represent service at a conference of health officers to be held at New Orleans, La., February 3, 1899. February 9, 1899.

WILLIAMS, L. L., Passed Assistant Surgeon. To proceed to Alexandria, Va., for special temporary duty. January 31, 1899.

Appointments.

COMFORT, NEWTON C., of Pennsylvania, and DAVIS, HENRY E., of Massachusetts, to be junior hospital steward. February 1, 1899.

MCGINNIS, R. H., of Florida, to be acting assistant surgeon for duty at the port of Jacksonville, Florida. January 28, 1899.

Promotions.

CARRINGTON, P. M., Passed Assistant Surgeon. Commissioned as surgeon. January 24, 1899.

HERTY, F. J., Junior Hospital Steward. To be senior hospital steward. January 26, 1899.

SCOTT, E. B., Junior Hospital Steward. To be senior hospital steward. February 1, 1899.

Society Meetings for the Coming Week:

MONDAY, February 20th: New York Academy of Medicine (Section in Ophthalmology and Otolaryngology); New York County Medical Association; Hartford, Connecticut, Medical Society; Chicago Medical Society.

TUESDAY, February 21st: New York Academy of Medicine (Section in General Medicine); Buffalo Academy of Medicine (Section in Pathology); Ogdensburg, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Societies of the Counties of Chemung (quarterly), Kings, and Livingston (quarterly), N. Y.; Baltimore Academy of Medicine.

WEDNESDAY, February 22d: New York Academy of Medicine (Section in Laryngology and Rhinology); New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Philadelphia County Medical Society.

THURSDAY, February 23d: New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopaedic Society; Brooklyn Pathological Society; Brooklyn Society for Neurology; Roxbury, Massachusetts, Society for Medical Improvement (private); Pathological Society of Philadelphia.

FRIDAY, February 24th: New York Clinical Society (private); New York Society of German Physicians; Yorkville Medical Association, New York (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

SATURDAY, February 25th: New York Medical and Surgical Society (private).

Births, Marriages, and Deaths.

Born.

GARCIN.—In Richmond, Virginia, on Wednesday, February 8th, to Dr. and Mrs. Ramon D. Garcin, a son.

Married.

BARTHOLOMEW—GROSCH.—In New York, on Monday, January 30th, Dr. H. S. Bartholomew and Miss Marie Grosch.

FLINT—SLOCOM.—In New York, on Tuesday, February 11th, Mr. Sherman Flint, son of Dr. Austin Flint, and Miss Margaret Olivia Slocom.

LEROSEN—HOPKINS.—In Lafayette, Louisiana, on Thursday, February 9th, Professor Wesley A. Lerosen and Miss Susie Hopkins, daughter of Dr. Thomas B. Hopkins.

McDONALD—BIRWELL.—In Ebenezer, Mississippi, on Wednesday, February 8th, Dr. John A. McDonald, of Durant, Mississippi, and Miss Pattie Birwell, daughter of Dr. William B. Birwell.

MOFFETT—LUSK.—In New York, on Saturday, February 11th, Mr. Cleveland Moffett and Miss Mary Lusk, daughter of the late Dr. William K. Lusk.

MCKEN—WILCKENS.—In Brooklyn, on Tuesday, February 14th, Dr. George Morgan Mcken and Miss Elizabeth Wilkens.

THOMAS—FOSTER.—In New Haven, on Wednesday, February 8th, the Rev. George Herbert Thomas and Miss Margaret Codrington Foster, daughter of Dr. John P. Foster.

Died.

BIGELOW.—In Amherst, Massachusetts, on Thursday, February 9th, Dr. Orvis F. Bigelow, in the sixty-fifth year of his age.

BISSELL.—In Buffalo, on Monday, February 6th, Lora Hudson Bissell, wife of Dr. E. L. Bissell.

BRANDT.—In Ontario Centre, N. Y., on Saturday, February 4th, Dr. John W. Brandt, aged seventy-five years.

CLARK.—In Kosciusko, Mississippi, on Tuesday, February 7th, Dr. Charles B. Clark.

ETHERIDGE.—In Chicago, on Friday, February 10th, Dr. James H. Etheridge, in the fifty-fifth year of his age.

HITCHCOCK.—In Hyde Park, Massachusetts, on Monday, February 6th, Katherine, infant daughter of Dr. Henry R. Hitchcock.

KEEGAN.—In Jersey City, on Friday, February 10th, Dr. J. Edward Keegan.

RUSSELL.—In Spartanburg, South Carolina, on Monday, February 6th, Dr. William T. Russell, in the seventy-second year of his age.

SLICER.—In St. Joseph, Louisiana, on Wednesday, February 8th, Dr. John Edwin Slicer, in the sixty-ninth year of his age.

Obituaries.

JAMES HENRY ETHERIDGE, M.D., OF CHICAGO.

THE death of Professor Etheridge, of the Rush Medical College, a distinguished gynecologist, inflicts serious loss upon the medical profession, not only of Chicago, but of the whole country. He was a native of the State of New York, but obtained his medical education in Chicago, where he practised from 1869 up to the time of his death. He was a frequent contributor to medical journals, and he was active in society work.

Special Articles.

THE LAW IN ITS RELATIONS TO PHYSICIANS.

By ARTHUR N. TAYLOR, LL.B.

(Continued from page 207.)

VI.

CONTRACT OF PHYSICIAN WITH PATIENT.

Contract Defined and Classified.—A contract has been defined by an eminent law writer of the early twentieth century as "an agreement upon sufficient consideration

to do or not to do a particular thing."^{*} This agreement may be express or implied. Where the particulars of the agreement are averred and mutually agreed upon, the contract is said to be an express contract; but where no particular terms are set forth, the law will take into consideration the relations of the parties, and will, by implication, create for them such an agreement as reason and justice would dictate. The contract is then said to be an implied contract. Such contracts may exist without our knowledge or volition, and, as a matter of fact, do arise from nearly every transaction into which we enter, thus constituting much the greater number of contracts by which we are bound.

Express contracts are either written or verbal. Written contracts are, as the name implies, reduced to writing and signed by the parties to be bound; while oral contracts are formulated only by word of mouth, and may be made either in the presence of witnesses or when the contracting parties only are present. In the absence of statutes which provide that certain contracts must be in writing, an oral contract is in all respects as binding as a written contract, the only advantage of the latter being the much greater ease and certainty with which the exact agreement is proved.

It will be readily understood from the preceding that whenever a physician or surgeon undertakes the treatment of a patient certain contracts are created by the law founded upon the relation of the parties. These contracts will be taken up and considered in the order in which they naturally follow.

Contract implied from Exercise of Professional Duties.—By merely undertaking the treatment of a patient the physician impliedly contracts with that patient that he has such skill, science, and information as will enable him properly and judiciously to perform the duties of his profession.[†] This is a contract which the law creates irrespective of any statutes prescribing qualifications for the practice of medicine, and one which was implied at common law before statutes existed upon the subject. The exact degree of this skill and knowledge which the physician is required to possess has many times been the subject of judicial consideration. It would be manifestly unjust to the physician or surgeon to require him to possess the highest degree of knowledge or skill, while, on the other hand, the public welfare requires that the standard be kept well above that of the tyro or quack. The courts have accordingly held in all cases submitted to them that he is by this implied contract required to be possessed of "proper," "reasonable," "ordinary" knowledge and skill.[‡] But whether or not the proper degree of knowledge and skill is brought to the particular case must be determined from the circumstances.

Advanced State of Medical Science to be considered.

It is a well-settled proposition of law that in fixing of the degree of knowledge and skill in any given case due regard must be had to the advanced state of the profession at the time.[§] If, for instance, an operation were to be performed upon the eye of a person whose physical condition was such as to render it unsafe to

put him under the influence of general anesthetics, it would be evidence of culpable ignorance and lack of skill for the operator to proceed by using other than local anesthetics; whereas about nineteen years ago recognized authorities on the subject laid down the rule that chloroform should always be administered.*

Opportunities of Location to be considered.—It will also be manifest that the opportunities and location of the physician, and more particularly the surgeon, are a very important factor in determining the degree of skill and proficiency which he should be reasonably expected to attain. In the larger cities the physician and surgeon has the opportunity of attending the hospitals and clinics, of witnessing and taking part in the most difficult and complicated operations, and of attending lectures and consultations whereby he is kept in constant touch with the ablest and most advanced of his profession; whereas in the small towns and country districts the physician and surgeon has fewer opportunities of observation and practice, especially in the line of surgical work, and can not reasonably be held to possess so high qualifications as his more favored professional brother.

The law takes this condition into consideration in determining the degree of skill and knowledge which a physician impliedly contracts to possess, and accordingly requires that he have the average skill and ability ordinarily possessed by men of his profession in *similar localities*.†

Test applied to all acting as Physicians.—This test of professional knowledge and skill is not applied to the regular qualified practitioner alone, but to any person who holds himself out as a healer of diseases, and who accepts employment as such.‡ Should, for example, one represent himself as qualified to treat and operate upon patients, who was ignorant of the most rudimentary principles of medicine and surgery, the law would extend to him no indulgence because of his unfortunate lack of scientific training, but in case deleterious results attended his treatment the same test would be applied in his case as in the case of the regularly qualified physician and surgeon practising in the same locality and at the same time—that is, he would be required to exercise at least the ordinary skill and ability possessed by physicians and surgeons in similar localities. Failing in this, he would be held to respond in damages to the extent of the injury suffered by reason of his incompetency.

Contracts to Use Care and Diligence.—The physician and surgeon also impliedly contracts that he will use reasonable and ordinary care and diligence in the exercise of his skill and the application of his knowledge to accomplish the purpose for which he is employed.¶ It is patent that a physician and surgeon may be possessed of a very superior degree of knowledge and skill and yet fail in the successful treatment of a case by not using the proper care in applying his knowledge or exercising his skill. For example, a physician of superior learning and skill might in the hasty or indifferent examination of a patient fail to observe symptoms characteristic of the disease from which the patient is suffering, and treat him for a different ailment with

disastrous results, while a physician with less skill and learning could by a more careful examination of the patient detect the true condition, and by applying the generally recognized remedies effect a cure.

To determine what is ordinary care and diligence no absolute rule can be prescribed. Justice Story, in referring to the impossibility of a fixed standard or test, said: "Different things may require very different care. The care required to build a common doorway is quite different from that required to raise a marble pillar, but both come under the description, ordinary care."* And so in the treatment of patients, that which in one case might be ordinary care would perhaps in another be gross negligence. The question is peculiarly one of fact, and can only be determined by taking into consideration the condition of the patient in the particular case, together with all of the attendant circumstances. If, after such an examination, it is found that the care and diligence exercised are those which an ordinarily careful physician, practising in a similar locality, would have exercised in a like case, then it is fair to conclude that the legal requirement of ordinary care and diligence has been fulfilled.

Degree of Care not Necessarily Proportionate to Character of Injury treated.—It must not be inferred from the foregoing description of ordinary care and diligence that the degree of care and diligence or care and skill necessary to be exercised in a particular case must be proportionate to the severity of that case. Such a doctrine has been urged but has been very wisely rejected by the courts.† If such a rule were adopted the conclusion would naturally and logically follow that a physician and surgeon is legally required to exercise care and skill adequate to the severity of all cases which he undertakes. Such a test is manifestly absurd and beyond the possibility of human requirements.

Refusal of Proffered Assistance does not Alter implied Contract.—The fact that a physician or surgeon refuses to accept the proffered assistance of other medical men does not increase his liability or responsibility, but simply amounts to an implied declaration that he possesses the ability which the law requires of him.‡

Physician's Contract unaltered where Services are Gratuitous.—Nor does the fact that a physician makes no charge and receives no compensation for treating a particular case alter in any degree the amount of knowledge, care, and skill which it is incumbent upon him to have and exercise.¶ In instructing a jury upon this question, Justice Pryor stated the law, together with the reason upon which it is based, so fully and clearly that we can do no better than to use his words: "It appears that the plaintiff was a charity patient; that the defendant was treating her gratuitously. But I charge you that this fact in no way qualifies the liability of the defendant. Whether the patient be a pauper or a millionaire, whether he be treated gratuitously or for reward, the physician owes him precisely the same measure of duty and the same degree of skill and care. He may decline to respond to the call of a patient unable to compensate him; but if he undertake the treatment of such a patient he can not defeat a suit for malpractice nor mitigate a recovery against him upon the principle that the skill and care required of a physician are

¶ *Du Bois v. Decker*, 130 N. Y., 325.

proportioned to his expectation of pecuniary recompense. Such a rule would be of the most mischievous consequence, would make the health and life of the indigent the sport of reckless experiment and cruel indifference." *

This rule must, however, be understood with the qualification that a party who undertakes the gratuitous treatment of another incurs no liability unless he professes to be a physician and undertakes the treatment as such. For if he merely gives his advice or assistance as a friend or neighbor he incurs no professional responsibility.† Where, for example, one not a physician, employed in the capacity of a midwife, attempted to treat the infant's eyes, and by reason of the inefficient remedies used the child became blind, the law would not hold the midwife as contracting to possess the same skill and learning as it would a regular physician who had gratuitously undertaken the same case.

Dentist's Contract implies Knowledge, Skill, and Care.—It may be observed in passing that a dentist implies by the exercise of the duties of his profession that he is possessed of the same amount of knowledge and skill in his profession, and will exercise the same degree of care and diligence in their application, as that impliedly contracted for by the physician in the medical profession.‡

Contracts to Use Best Judgment.—In addition to the contract of the physician implying that he is possessed of learning and skill and will exercise reasonable care and diligence in the treatment of his patients, it also implies that in all cases of doubt he will use his best judgment. The contract is not that his judgment will be infallible, but simply that it shall be a reasonably good judgment, and that in all cases of doubt he will fully exercise it.

In the abstract this rule appears to mean very little, but when it comes to the particular case: when the physician finds his patient suffering, perhaps, with conditions symptomatic of several diseases; when by the exercise of his best knowledge and skill, or, for that matter, the best knowledge and skill of the most enlightened of his profession, he can not determine the patient's exact condition; then the rule has a real meaning to him. In such an emergency it can not fail to be a great comfort and relief to know that an intelligent and careful exercise of his best judgment is all that is required.

If, by way of showing a further application of the rule, a surgeon is requested by a patient to perform a certain operation which, in the opinion of the surgeon, is unwise, unnecessary, or will result injuriously to the patient, it becomes his duty to give the patient the benefit of his judgment, whether it is asked for or not, and if the surgeon fails to advise against such operation, but acts as requested, he becomes liable to the patient in damages for whatever injuries result to him by reason of such unnecessary or unwise operation. But, if the patient is of mature years and of sound mind, and upon being advised of the impropriety of such operation still insists upon its performance, the surgeon may accept the judgment of the patient, and, if the operation is skillfully and properly performed, he can not be held responsible to the patient because its result is injurious.

(To be continued.)

Letters to the Editor.

THE LICENSE TO PRACTISE IN INDIANA.

COLUMBUS, OHIO, February 7, 1899.

To the Editor of the New York Medical Journal:

SIR: Will you allow a suggestion or probably better a correction?

On page 169 (Mr. Arthur N. Taylor's article) he says: "In Indiana the license to practise is not granted by a State board and recorded in the particular county in which the physician intends to practise," etc. The fact is that that is just what is and must be done to-day. Mr. Taylor is two years behind in the law regulating the practice of medicine in the State of Indiana. And previous to the passage of the bill creating a State board it was necessary to be registered by a county clerk, and that registration entitled the holder to practise not only in that county but anywhere in the State. I would advise Mr. Taylor to write to the secretary of the State board of medical examination and registration of Indiana for a copy of the law. A. J. MILLER, M. D.

Proceedings of Societies.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Meeting of November 2, 1898.

The President, Dr. S. ALEXANDER, in the Chair.

(Continued from page 158.)

Electro-hæmostasis in Surgery.—Dr. A. J. SKENE read a paper with this title. (See page 223.)

Dr. W. M. POLK asked Dr. Skene how far the heat extended beyond the electrode, because he was interested in the possible consequences in an operation such as vaginal hysterectomy.

Dr. SKENE replied that the shield forceps, applied in front and behind the compression forceps, protected the ureter in front and the rectum behind, and the heat did not extend into the broad ligament more than from a line to an eighth of an inch.

Dr. POLK said that this answer showed that, from this standpoint, the method was free from criticism. Unfortunately, all that he knew about the subject was from Dr. Skene's paper, but this, in itself, was enough to make him endorse the treatment. The large number of cases in which the method had been employed without secondary hemorrhage would seem to place it on the basis which would lead to its adoption by every operator. But, notwithstanding his confidence in Dr. Skene's carefulness and work, he personally confessed a good deal of timidity in taking up this work. This was, of course, no valid excuse, because it could apply to every new method that had been brought forward. If one were once fully equipped with the necessary electrical apparatus, there should be no reason why any other surgeon should not be able to do it successfully and results.

Regarding the use of heat in the treatment of cancer, in the paper, he was inclined to agree with Dr. Skene's admirable advice that he would not recommend it. There is no present and no future in the use of heat in the treatment of cancer, and the only way in which it can be used is in the treatment of the cancer of the breast.

known that the ligature *en masse* was a defective method, and was, therefore, avoided whenever possible by good operators. If the blood-vessels could be isolated and individually ligated, he believed there was no ground for the criticism made in the paper concerning the subsequent shrinkage of the stump and the consequent danger of secondary hæmorrhage. The danger of contamination of a ligature when applied to a suppurating surface was, of course, a real one, but the number of cases coming into the hands of any single individual was comparatively small. He believed that even in these cases the ligature could be applied in a space that could be made so aseptic as to annul that criticism. Again, the reader of the paper had said that these ligatures frequently cut through the tube and became infected in this way, although originally perfectly aseptic, and that this contamination prevented the absorption of the ligature. This danger had been so thoroughly recognized that many operators made it a rule never to ligate a tube, but to dissect it out as far as the cornu of the uterus, and then close the opening by the application of several fine silk sutures, such as were used in ordinary intestinal operations. The application of the ligature almost exactly as Ambroise Paré in 1560 suggested and urged would relieve it from very many of the criticisms suggested. The speaker said that he could not add one word regarding the use of electro-hæmostasis, but he intended to follow Dr. Skene's suggestions as soon as opportunity offered.

Dr. CLEMENT CLEVELAND said he regretted exceedingly that he did not possess the powers of speech of the gentleman who had just spoken, for he had had experience with the method. When he had first learned of the method, a year and a half ago, he had begun its use and had employed the instruments almost constantly since then. His experience with it led him to agree most thoroughly to all the points made in the paper. He had not been able to secure all of the instruments and had therefore used the larger clamps in the hysterectomies and the removal of the larger ovarian tumors. He found that the statement made regarding the aseptic condition of the tissues and the devitalization of the nerves had been confirmed in his own experience, because these patients had suffered much less pain than those operated upon in the usual manner. He had not found it necessary to employ the instrument specially devised for use on the pedicles of ovarian tumors, for the reason that it was his practice to twist the pedicle into a cord so as to prevent it from spreading. Very rarely had he found it necessary to reapply the forceps. He had been in the habit of placing gauze or sponges around the forceps to prevent the burning of the adjacent tissues, but would hereafter use the special shields. He had never injured the ureters in any operation in which this forceps had been used. He employed the street current, modified by a transformer, and ordinarily left the forceps on for three minutes, fearing to remove them more quickly. The current strength had usually been six amperes. He had nothing but words of commendation for the method, and would be very sorry now to be deprived of these instruments.

Dr. W. R. PRYOR said that, accepting all that had been written by Dr. Skene regarding hæmostasis *en masse*, he had instituted a series of experiments regarding the effect of the method when blood-vessels were treated in continuity. The blood vessel selected was the third in size in the human body—the external or internal iliac or the femoral. The forceps had been applied, and

then the blood-vessel had been tested to see what pressure was required to blow out the inspissated end. He had found that a ligature force of three pounds would always bring about complete coaptation, and that a force of thirteen pounds within the blood-vessel was required to overcome the agglutination brought about by the electricity. This was only true when the clamp was applied at a right angle to the blood-vessel, and that when the blood-vessel was seized, as it usually was, by the end of the clamp, much less pressure would blow out the end. The surgeons of the present day were in the habit of ligating in continuity. It was interesting to note that, without charring the tissues at all, an occlusion could be obtained which was four times stronger than the force exerted by the heart.

Dr. FREDERICK HOLME WIGGIN said that he had not had any personal experience with electro-hæmostasis. He thought, with Dr. Polk and Dr. Pryor, that it was entirely feasible to employ ligatures which were perfectly satisfactory, such, for example, as catgut treated by the formalin method and boiled before using. The trouble experienced in the past from the use of the cautery for the control of hæmorrhage had been that the heat had been too high. This had apparently been obviated by Dr. Skene, and hence the method should prove very useful, especially in pelvic work.

Dr. C. C. BARNOWS said that he would give the method a trial as soon as an opportunity was afforded. The only theoretical objection in his mind had been the question as to its safety, but this seemed to have been pretty definitely settled.

Dr. A. B. JOHNSON asked Dr. Skene whether he had employed this method in operations in which a very large number of small blood-vessels had had to be controlled—as, for instance, in operations for the removal of the breast, or for extirpation of a tumor of the neck—and, if so, as to whether time was lost or gained. He would also like to know whether in the treatment of hæmorrhoids the period of convalescence was shortened or rendered more protracted by the electric method. The method seemed to him extraordinarily attractive, and he was anxious to try it.

Dr. R. A. MURRAY said that he noticed all of the instruments exhibited looked extremely well, and consequently he would like to know how much of the control of hæmorrhage was due to the perfect instruments and how much to the electricity. The comparatively slight heat certainly could not accomplish what Keith used to with the cautery iron and clamp. In his opinion, if the instruments were clamped and left on for three minutes without any electric current there should be hæmostasis. In making an abdominal incision where there was a good deal of hæmorrhage, he would like to know whether Dr. Skene would apply the small forceps and obliterate the blood-vessel by the electric current before opening the abdominal cavity. If this was his practice, did not the blood-vessels so treated interfere with the healing of the abdominal wound? Another interesting point in this connection was as to whether the method was applicable in controlling numerous bleeding points deep in the pelvis, and at the same time keep the tissues aseptic. It seemed to him from theoretical considerations that the parts that had been grasped by the forceps would be likely to become septic.

Dr. A. BROTHMAN asked if the method did not unduly prolong the operation, and if the apparatus was not too cumbersome for use in private, and particularly in cases seen out of town.

Dr. R. T. MORRIS said that on general principles it was well to do away with the ligature, provided a method could be substituted which was equally good. He would like to know whether it was Dr. Skene's intention to have surgeons employ this method to the exclusion of others. For instance, he frequently enucleated suppurating tubes or adherent masses in the pelvis, and afterward closed large bleeding veins by a number of very fine catgut sutures. He could insert eight or ten such sutures quite rapidly and control venous hemorrhage which could not be checked by the application of antipyrine.

Dr. R. H. WYLIE asked if any difficulty had been experienced in applying the method where there was bleeding deep in the pelvis, and a good deal of fluid surrounded the forceps, as in cases of ascites. He would like to know whether there was any appearance of the tissues which could be used by the surgeon as an indication of the completion of the hemostasis before taking off the forceps. If we depended upon the ampèremeter, it must be unreliable, because the amount of electricity would vary with the amount of tissue included in the grasp of the forceps and with the presence or absence of fluids about it.

Dr. SKENE closed the discussion. He said that electro-hemostasis was more certain than the application of the ligature, and, moreover, it was impossible with the ligature to leave the stump of a pedicle or artery in septic tissue as clean and as free from sepsis, and as sure to make rapid repair, as where the method advocated in the paper was used. But the great point of superiority of the method of electro-hemostasis over the ligature was not in ligation of arteries alone, but in the closing of canals lined with mucous membrane. There never lived a surgeon who could be sure when he had tied a canal lined with mucous membrane that it would remain closed; it was well known that a great many of them would reopen. The later writings of Professor Rice, of Chicago, showed that in many cases the Fallopian tube opened and septic material escaped into the peritoneal cavity, resulting again and again in inflammations there. Dr. Polk had referred to this difficulty indirectly when he had stated that this could be obviated by resection of the tube at its insertion in the uterus. This practice, however, was very recent, and had not been tried by many surgeons, and, therefore, remained doubtful, to say the least. With a septic uterus and septic tubes one could not close the opening with any kind of suture and absolutely prevent secondary infection. He could state this positively, because he had tried it. The same remark applied to the closure of the vermiform appendix. Even Dr. Morris, he thought, would acknowledge that he had seen faecal fistula from reopening of the appendix because of the adoption of faulty methods. If it were closed in the way he described, it would be found that it would not reopen. More than this, he could close up the appendix close to the intestine without the heat injuring the bowel. He maintained that by his method the process of repair was shorter, and the subsequent results very much more satisfactory. There were more permanent cures after salpingectomy when this method was used than with any other. Being familiar with the work of Dr. Cleveland, he felt that the approbation of such a surgeon was all that the most ambitious could desire. Regarding the pressure experiments made by Dr. Price, he could say that he had made the same experiments with the same results. He was of the opinion that if properly treated the arteries could not be opened by any means—even by dissection. With reference to Dr.

Johnson's questions, he would say that he had extirpated the mammary gland and had been able to control the blood-vessels as rapidly as he had ever been able to do it with the use of ligatures, but he had done it by keeping several arteries under the electrical treatment at a time, which could be done with the help of skilled assistants. There was no more vascular condition than in omental adhesions in certain large ovarian and fibroid tumors, yet he could close those blood-vessels by the clamp more quickly than by the use of the ligature, and avoid entirely ripping up of the omentum, which caused bleeding that was difficult to control. He used to dread treating varicose veins of the labia, but now he simply incised the skin, picked up the blood-vessels with the clamp, and, in one or two minutes, he reduced the mass of blood-vessels to a fine ribbon of tissue, which could be left in the wound without fear of subsequent trouble. Convalescence after the application of electro-hemostasis to hemorrhoids was as quick as by any other method, and was much less painful than when the old cautery method or ligature was used. In the removal of papillomatous growths from the bladder after suprapubic cystotomy, he found it was only necessary to expose them, desiccate them, and clip them off, leaving only small stumps. The same practice could be followed with satisfaction in the treatment of bleeding vessels deep down in the pelvis. It would be impossible to treat bleeding vessels in Douglas's cul-de-sac if the cavity was filled with blood, but he never experienced any difficulty from this source, because in his abdominal work he always kept beside him an immense aspirator, with which he could quickly remove the fluid. With this instrument he could draw off two gallons of fluid from the abdominal cavity in from a minute to a minute and a half. After the fluid had been removed in this way, the electro-hemostasis could be successfully employed. It was impossible to tell whether the desiccation had been completed before the removal of the forceps, just as it was in the application of the ligature to a blood-vessel. The experienced surgeon knew pretty well by touching the forceps with the finger whether or not the heat was sufficient, and whether the process had probably been completed. When he opened the abdominal cavity it was his practice to seize the blood-vessels with small forceps for not longer than half a minute. There was no interruption to immediate union when the hemorrhage was controlled in this manner.

Book Notices.

On the Origin and Progress of Renal Surgery. With Special Reference to Stone in the Kidney and Ureter, and to the Surgical Treatment of Calculus of the Ureter. Being the Hunterian Lectures for 1898. By other with a Critical Examination of Subsequent Lectures of the Ureter. By HENRY MORRIS, M.A., M.B. Lond., F.R.C.S., Hunterian Professor of Surgery and Pathology, Royal College of Surgeons of England, etc. Philadelphia: P. B. Blakely, Son & Co., 1898. Pp. viii+288. 11s. 6d. 8s. 6d.

This work will be of great value to the student of surgery, so closely does it touch upon the subject of which it treats. The treatment of the ureter is a part both historical and practical, and the author has done his

press one with the remarkable progress that has been made in the surgical treatment of diseases of the kidney and ureter during the past few years and the not less remarkable advance in conservative methods of procedure. Nephrectomy has become less and less the operation of choice, owing to the greatly diminished percentage of mortality that has been shown to follow nephrotomy and nephrolithotomy, and to the fact that the affected kidney retains its functional activity to a greater or lesser degree after either of the latter operations.

In the second lecture the many difficulties in the diagnosis of renal calculus are discussed at length, together with the dangers of quiescent and unsuspected calculi. This lecture is rather of the nature of a plea for better diagnosis and earlier operation, a plea that we think is distinctly justified by the results of late operation and, unfortunately only too often, by post-mortem findings.

The third lecture treats of calculous anuria in detail, the pathology, symptoms, and diagnosis, and of the technics of the exploration of the kidney and ureter for calculus. The necessity of thoroughness is insisted on, and all such methods as needling and external palpation are discountenanced as insufficient to determine the presence of small stones. The extraperitoneal method of exposing the kidney through a lumbar incision is the only one described, for by it not only the kidney but the ureter as far as the pelvic brim can be explored and, if need be, operated upon. If it becomes necessary to open the pelvis of the kidney directly, Morris recommends that the wound be closed by suture in most cases.

This ends the Hunterian Lectures, but a chapter is added upon injuries of the ureter, and a large number of tabulated cases forms by no means the least valuable part of this excellent little book.

Atlas of Methods of Clinical Investigation, with an Epitome of Clinical Diagnosis and of Special Pathology and Treatment of Internal Diseases. By Dr. CHRISTERED JAKOB, formerly First Assistant in the Medical Clinic at Erlangen. Authorized Translation from the German. Edited by AUGUSTUS A. ESNER, M. D., Professor of Clinical Medicine in the Philadelphia Polyclinic, etc. With One Hundred and Eighty-two Colored Illustrations upon Sixty-eight Plates, and Sixty-four Illustrations in the Text. Philadelphia: W. B. Saunders, 1898. Pp. 259. [Price, \$3.]

It is probable that by acquaintance with other volumes of this series of atlases our readers are familiar with the character of the works and the object with which they have been produced. It is indisputable, as the Note to the Editor says, that "a good illustration will often convey more and leave a deeper impression than the most elaborate description." For this reason there have been grouped in this volume a most excellent collection of colored plates illustrative of the methods of clinical investigation, microscopical and chemical, to which is added a descriptive text. This text is good, does not differ materially from that found in the smaller works upon clinical diagnosis, and is subordinate to the pictorial representations. Of these pictures—the major element of the book—admiration and approval may be expressed. The plates portraying microscopical appearances are almost uniformly good, those of chemical appearances are good for the greater part, though occasionally of undue splendor of color, and those which are

diagrammatic representations of thoracic and of abdominal diseases are the best of all. The use of colors in these diagrams and the ingenuity of the diagrams themselves can not fail to assist the student in his pursuit of the mysteries of physical diagnosis.

Lectures on the Theory and Practice of Vaccination.

By ROBERT CORY, M. A., M. D. Cantab., F. R. C. P. Lond., Physician in Charge of the Vaccination Department of St. Thomas's Hospital, etc. New York: William Wood and Company, 1898. Pp. 122.

THESE six lectures will afford the medical reader much satisfaction, for they ably cover a field in which we are all perforce interested, and they represent the views of one to whom long experience with vaccination and all that pertains to it has given clear title to be regarded as an authority.

The first lecture is devoted to the reasons for the vaccination laws which now are found so generally among civilized peoples. Naturally this chapter is both historical and statistical, and to all but the hopelessly bigoted must be most convincing. The second chapter concerns the histology of vaccine and of small-pox vesicles. The third chapter shows wherein a secondary vaccination differs from the primary. The fourth chapter is descriptive of eruptions that sometimes follow vaccination, but its value is considerably marred by some absurd plates which in this day of superior illustrations are inexcusable. The fifth chapter details the practice of vaccination, and the sixth discusses in a remarkably interesting manner the relations existing between small-pox on the one hand and cow-pox, horse-pox, and camel-pox on the other. The work is one of very great value.

Political Crime. By LOUIS PROAL. With an Introduction by Professor FRANKLIN H. GIDDINGS, of Columbia University. New York: D. Appleton and Company, 1898. Pp. xxii-355. [Price, \$1.50.]

THE treatise which Proal has written upon political crime—by which term is here intended the crime of which governments are not the victims but the authors—is masterly, as might have been expected. The subject is a vast one and one which, however morality may urge its study, sophistry and the plea of necessity have always been too apt to distort. It is pleasant, therefore, to become possessed of a work which adequately treats of the subject, and one whose author refuses to be guided in his judgments by aught save right, and who, moreover, has the ability to sustain his judgment by well-supported proof.

It may be said that political crime can be regarded as in no sense a medical topic, or one only by the greatest stretch of the imagination. In a measure this is true, for, though governments may or may not be individuals, classes and bodies and epochs are subject to epidemic influences of a psychological kind. Apart from this, however, the study of politics is one which concerns every man, be he or be he not a physician, and nobody who thinks can fail to derive pleasure and profit from the thoughtful perusal of this masterly work. Too often, we think, the physician is apt to hold himself, or to be held, apart from the community, and therefore not receptive of matters which are not technical. This is unfortunate and far from what should be, for by circumstances and ordinarily by education the physician is well equipped to be a leader in the com-

munity and an agent politically for the public good. "Politics" should not be a despicable thing to any man, and least of all to one who bears the responsibilities which education imposes. Be he physician or layman, then, his conception of political science can not but be broadened by a work like this.

The Medical News Pocket Formulary for 1899. By E. QUIN THORSTON, M. D., Demonstrator of Therapeutics, Pharmacy, and Materia Medica in the Jefferson Medical College, Philadelphia. Philadelphia and New York: Lea Brothers & Co., 1899. Pp. 272. [Price, \$1.50.]

Saunders's Pocket Medical Formulary. With an Appendix containing Posological Table; Formule and Doses for Hypodermic Medication; Poisons and their Antidotes; Diameters of the Female Pelvis and Foetal Head; Obstetrical Table; Diet List for Various Diseases; Materials and Drugs used in Antiseptic Surgery; Treatment of Asphyxia from Drowning; Surgical Remembrancer; Tables of Incompatibles; Eruptive Fevers; Weights and Measures, etc. By WILLIAM M. POWELL, M. D., Member of the Philadelphia Pathological Society, etc. Fifth Edition, thoroughly revised. Philadelphia: W. B. Saunders, 1899. Pp. 290. [Price, \$1.75.]

THESE booklets contain a large number of standard prescriptions in a form easily accessible for reference, and if used with discrimination will prove helpful in practice.

Suite de monographies cliniques sur les questions nouvelles en médecine, en chirurgie, en biologie. No. 11. Les paralysies générales progressives. Par le Dr. M. KLUPPEL, Médecin des hôpitaux de Paris. Pp. 25. No. 12. Le myxodème. Par le Dr. G. THIBERGIE, Médecin de l'hôpital de la Pitié. Pp. 32. Paris: Masson et Cie., 1898. [Chaque monographie séparément 1 fr. 25.]

THESE two brochures constitute the eleventh and twelfth clinical monographs in the *Œuvre médico-chirurgicale* published under the direction of M. Critzman. They are useful presentations of the subjects of which they treat.

BOOKS, ETC., RECEIVED.

A Practical Treatise on Fractures and Dislocations. By Lewis A. Stimson, B. A., M. D., Professor of Surgery in Cornell University Medical College, etc. With Three Hundred and Twenty-six Illustrations and Twenty Plates in Monotype. New York and Philadelphia: Lea Brothers & Co., 1899. Pp. xiv 49 to 818. [Price, \$5.]

The American Yearbook of Medicine and Surgery. Being a Yearly Digest of Scientific Progress and Authoritative Opinion in all Branches of Medicine and Surgery, drawn from Journals, Monographs, and Text-books of the Leading American and Foreign Authors and Investigators. Collected and arranged with Critical Editorial Comments by Samuel W. Abbott, M. D., John J. Abel, M. D., J. M. Balby, M. D., Charles H. Burnett, M. D., J. Chalmers Da Costa, M. D., W. A. Newman Dorland, M. D., Louis A. Duhring, M. D., D. L. Edsall, M. D., Virgil P. Gilney, M. D., Henry A. Griffin, M. D., John Guerrier, M. D., C. A. Hamann, M. D., Alfred Hand, Jr., M. D., Howard F. Hansell, M. D., Milton B. Hartzell, M. D., Barton Cooke Hirst, M. D., E. Fletcher Ingals, M. D., Wyatt Johnston, M. D., W. W. Ken,

M. D., Henry G. Olds, M. D., Wendell Robert, M. D., David Riesman, M. D., Louis Starr, M. D., Alfred Stengel, M. D., G. N. Stewart, M. D., J. R. Tillinghast, Jr., M. D., and J. Hilton Waterman, M. D., under the General Editorial Charge of George M. Gould, M. D. Illustrated. Philadelphia: W. B. Saunders, 1899. Pp. 4 to 1102. [Price, \$6.50.]

Diet in Illness and Convalescence. By Alice Worthington Winthrop. Profusely Illustrated. New York and London: Harper & Brothers, 1899. Pp. vii-3 to 287.

Fever-nursing: Designed for the Use of Professional and Other Nurses, and especially as a Text-book for Nurses in Training. By J. C. Wilson, A. M., M. D., Visiting Physician to the Hospital of the Jefferson Medical College and the Pennsylvania Hospital, etc. Third Edition, revised and enlarged. Philadelphia: J. B. Lippincott Company, 1899. Pp. 3 to 241. [Price, \$1.]

Three Thousand Questions on Medical Subjects arranged for Self-examination. With the Proper Replies to Standard Works in which the Correct Replies will be Found. Second Edition, enlarged. Philadelphia: P. Blakiston's Son & Co., 1899. Pp. viii-9 to 189. [Price, 10 cents.]

Golden Rules of Surgical Practice. By E. Harry Fenwick, F. R. C. S., Surgeon to and Lecturer on Clinical Surgery at the London Hospital, etc. Golden Rules Series. No. 1. Fifth Edition, revised and enlarged. London: Simpkin, Marshall, Hamilton, Kent, & Co., 1899. Pp. vi-10 to 71. [Price, 1s.]

Golden Rules of Gynecology. By S. Jervois Aarons, M. D., Registrar to the Hospital for Women, etc. Golden Rules Series. No. 2. London: Simpkin, Marshall, Hamilton, Kent, & Co., 1899. Pp. 11 to 63. [Price, 1s.]

Golden Rules of Obstetric Practice. By W. E. Fothergill, M. A., B. Sc., M. D., Author of *A Manual of Midwifery*, etc. Golden Rules Series. No. 3. London: Simpkin, Marshall, Hamilton, Kent, & Co., 1899. Pp. 4 to 71. [Price, 1s.]

Archives of the Röntgen Ray (formerly Archives of Skiagraphy). Edited by Thomas Moore, F. R. C. S., Surgeon to the Miller Hospital, and Ernest Payne, M. A. (Cantab.), etc. London: The Rebus Publishing Company, 1898. Pp. 45 to 63.

Transactions of the Luzerne County Medical Society for the Year ending December 31, 1898. Volume VI.

Report of the Sewage Commission to the General Assembly of the State of Connecticut. January Session of 1899.

Eighth Annual Report of the State Board of Medical Examiners of New Jersey. 1898.

Manual of Examinations for the Classified Civil Service of the United States. (Revised to January 1, 1899.) United States Civil Service Commission.

Thirty Poisonous Plants of the United States. By V. K. Chesnut, Assistant Botanist, United States Department of Agriculture. Farmers' Bulletin No. 86.

Combined Typhoid and Malarial Infection. Report of a Case and Review of the Literature, with Special Reference to the So-called Typhoid and Malarial Fever. By Irving Phillips Lyon, M. D., of R. I. (Reprinted from the *American Journal of Medical Sciences*.)

A Case of Concentric Displacement of the Heart to the Right, presenting Some Unusual Features. By Charles Lyman Greene, M. D., of St. Paul, and J. L. Rothrock, M. D., of St. Paul. (Reprinted from the *Philadelphia Medical Journal*.)

Miscellany.

Sudden Death during the Puerperium.—M. Porak and M. Durante (*Gazette hebdomadaire de médecine et de chirurgie*, December 22, 1898) communicated recently to the Obstetrical and Gynecological Society several cases of sudden death during the puerperium. In one case the patient was the subject of old-standing cardiopathy. In another, the woman was rendered very anemic by severe hemorrhage, rendering necessary transfusion of blood. In a third, sudden death was occasioned by a gaseous embolus consequent upon an intra-uterine injection.

In a recent case, a woman who had been lately confined at the Maternity, the confinement being normal save for a slight hemorrhage, had a rise of temperature on the fifth day to 100.4° F. without any corresponding symptoms as regarded her general condition. Subsequently her temperature fell to normal and nothing gave reason to fear any complications. On the ninth day, during her breakfast, she fell abruptly from her bed, and was found to be dead. At the autopsy a double uterus was found, as had been known to be the case during life. There was only one kidney. In seeking for the cause of death it was found in embolism of the large branches of the pulmonary artery. The clots found in these vessels were non-adherent. The point of origin of the embolus was discovered at the extremity of the right hypogastric vein, which was affected with endophlebitis with a small adherent clot. The histological examination showed infectious endophlebitis, probably due to *Bacillus coli*. Numerous colonies of the bacillus were found in the clot which was beginning to organize. The authors point out that though the presence of this germ is common in the organs after death, in this particular case the microbes were contained in migratory cells in process of organization.

Primary Epithelioma of the Uvula.—Dr. Walker Downie (*Scottish Medical and Surgical Journal*, January) reports, in view of the acknowledged rarity of this condition, a case of epithelioma arising in the uvula.

Pseudo-tuberculosis of Feline Origin.—M. Galaville (*Nouveau Montpellier médical*, January 1st) concludes as the result of a series of experiments, the details of which he records, that there is probably existent in felines a bacillary tuberculosis analogous to those which have been described under the name of pseudo-tuberculosis of the guinea-pig, mouse, rabbit, and sheep. The brain of a cat was used for inoculation, and from it this disease was produced in two different species of animal, thus eliminating the hypothesis of coincidence. The author has also reproduced the disease in many cats.

The Treatment of Subinvolution of the Uterus.—According to the *Indian Medical Record* for December 16th, Dr. Baldy teaches that in a slow involution of the womb after miscarriage or abortion, as well as in subinvolution after labor, the daily irrigation of the uterine cavity with a gallon of a mild alkaline antiseptic solution of a high temperature, 110° to 115° F., promotes prompt involution.

Osteoma of the Brain. M. Leclerc (*Lyon médical*, January 14) recently, presented to the National Medical Society of France, a portion of an osteoma from a patient who had infantile hemiplegia and hemisthesia. The

autopsy showed an osteoma of the left optic thalamus. The patient succumbed to a recent softening of the opposite cerebral hemisphere. The hemisphere on the side containing the osteoma was greatly diminished in volume. There did not appear to be any atrophy of the cerebellum. In response to M. Destot, M. Leclerc said that chemical analysis proved the tumor to consist of osseous tissue. The microscopical examination was not yet completed.

Fear Neurosis.—Dr. Morton Prince (*Boston Medical and Surgical Journal*, December 22d) describes under this term a condition in which, although the symptoms are the natural physical manifestations of fear, nevertheless they are not accompanied by this emotion, but exist independently of any psychical state as a group of pure physical symptoms. Hence the term phoboneurosis is more exact than phobopsychosis.

Two sets of causative factors, he says, must be distinguished:

1. A natural or excessive timidity at the beginning, in consequence of which certain external conditions have repeatedly excited fear and its physiological manifestations (tremor, palpitation, faintness, etc.). By a constant repetition, as would necessarily be the case with a musician, for example, these physical symptoms become welded together into an automatic process which persists as a true habit neurosis. This may be looked upon as a sort of degeneration of nervous processes by which frequently associated actions become grouped together. Physiologically, this is the same principle by which any art (violin playing, fencing, rowing) is learned; pathologically, it is the basis of many neuroses and psychoses. After a time, as a result of maturer years and experience, the psychical emotion, fear, subsides, but the physiological manifestations persist—an apparent paradox.

2. After the neurosis has become developed the immediate exciting cause of each individual attack is a primary auto-suggestion in the form of apprehension or expectation that the symptoms will come on under such and such circumstances, such as playing in public, and a secondary direct excitation by the act itself in accordance with the primary auto-suggestion. Such, at least, is the theory which seems to him to best explain the phenomena. But whether or not this is the correct interpretation of the genesis of the neurosis, the existence of the neurosis itself is, it seems to him, unquestionable.

The author next describes in considerable detail three cases that came under his own observation, and from these the symptomatic phenomena may be stated as follows:

In the first case, that of a professional singer, thirty years of age, the author was consulted for the following symptoms: Whenever the patient sang in public he was affected with—1. A feeling of "goneness" and general trembling. 2. Throbbing in the head. 3. Palpitation. 4. Perspiration. 5. General weakness. The same group of symptoms always appeared and in the same order. The trembling was objective, so that he could with difficulty hold his music.

The second was that of a professional musician of well-known reputation.

The symptoms of the neurosis in this case began about ten minutes before playing, and continued with exacerbations and remissions during the whole time while playing. When they developed they did so with a rush in the following order: 1. Dryness of the throat.

2. A feeling like that of indigestion. 3. Hands cold and moist. 4. Palpitation. 5. A sort of ataxia or clumsiness of the hands, so that he failed to have complete control over his instrument, in consequence of which he was much hampered in the practice of his art. This was the main reason for asking advice.

In consequence of this ataxia or clumsiness in the movement of his fingers he could not play so well in public as in private. Upon these symptoms followed certain mental disturbances, which were described as a lack of confidence in his ability to do himself justice, self-consciousness, and an irritability of temper.

In the third case, that of a professional man, the symptoms are recapitulated as follows: 1. Consciousness of being looked at. 2. Faintness. 3. Perspiration. 4. Flushing of the face. 5. Confusion of thought. 6. Depression, etc. The first five symptoms are the physiological manifestation of emotion.

The general principles of treatment are of the character of suggestion—as an instance in the case of the last patient, the author's plan was to create artificially in the patient's mind a fixed idea which should comport with the truth on the one hand, and be antagonistic to, and therefore inhibit, the morbid idea and its consequences on the other. To this end the following was written on a piece of paper:

"These symptoms are only physical processes which by habit have become associated together by a previous pathological mental state. This mental state having subsided, the association will subside and I have nothing to apprehend."

This was changed later to:

"I know I am the equal of the others. These symptoms are only physical processes which by habit have become associated together by a previous lack of confidence in my ability. Having now regained this confidence and knowing that I am the equal of others, this association will subside."

This he was told to learn by heart, and to repeat constantly to himself on every possible occasion—when he was alone, as he walked the streets, the last thing before going to sleep, and especially before undertaking his professional work in public.

The result was decidedly favorable.

Endemic Goitre.—Dr. Daniel McKenzie (*Glasgow Medical Journal*, January) thus concludes a paper on this subject:

To sum up, the modern view of goitre is that it is a disease caused by a *contagium vivum*, limited to certain areas for some unknown reason, existing in the soil and reaching man by drinking-water or unclean hands. I should add that the organism when introduced into the body induces an increased demand for thyroid secretion, which the gland hypertrophies to supply. Much has been said of the organism, but does not seem to go so far.

And the proofs I have adduced in favor of this idea are:

1. The gland enlargement is accompanied by no constitutional disturbance.

2. The microscopic appearances of the primary changes are those of a gland hypertrophied and active.

3. Treatment by thyroid is followed by reduction in size of the gland, which stops if the remedy is stopped.

4. The successful removal of a goitre by radical treatment has been followed by symptoms due to deprivation of increase in gland secretion.

Sporadic goitre may also be explained in a similar manner.

Volvulus of the Stomach.—The *Kansas City Medical Record* for January quotes the following from an exchange, the name of which is not specified: Berg (*Centralblatt für Chirurgie*, September 3d) describes two cases of twisting of the stomach upon its axis, the diagnosis not resting merely upon the symptoms which were present, but being confirmed by operation. In both instances the operation was followed by entire success. From the character of the lesion the name volvulus of the stomach seems a suitable one.

Smokers' Teeth.—The *Ohio Dental Journal* for January, quoting the *Weekly Dentist*, says that it has been found that the teeth of smokers are less liable to decay than those of non-smokers. It has also been found by scientific research that *L. pyothrix buccalis* and the other germs found in the mouth are rendered innocuous by tobacco smoke, and it is an established fact that it also entirely destroys or retards the development of the bacillus of cholera, of anthrax, and of pneumonia.

A Bill to Rid Illinois of Diploma Mills.—The following bill was introduced into both houses of the Illinois legislature on February 2d, and we are glad to learn that there is little or no doubt of its passage:

Be it enacted by the people of the State of Illinois, represented in the general assembly, that section two of an act concerning corporations, approved April 18, 1872, in force July 1, 1872, be, and the same is hereby, amended so that the same shall read as follows:

SECTION 2. Whenever any number of persons, not less than three nor more than seven, shall propose to form a corporation under this act, they shall make a statement to that effect under their hands, and duly acknowledged before some officer in the manner provided for the acknowledgments of deeds, setting forth the name of the proposed corporation, the object for which it is to be formed, its capital stock, the number of shares of which such stock shall consist, the location of its principal office, and the duration of the corporation, not exceeding, however, ninety-nine years; which statement shall be filed in the office of the secretary of State. The secretary of State shall thereupon issue to such persons a license, . . .

And, provided, further, that the secretary of State shall not issue charters to persons, associations, or corporations for the purpose of conferring degrees, diplomas, or other certificates of qualification in the science of medicine, pharmacy, or dentistry unless the application therefor is approved by the State board of health, the State board of pharmacy, or the State board of dental examiners, respectively. And, provided, further, that the secretary of State is hereby empowered, and it shall be his duty, to revoke charters issued to persons, associations, or corporations which authorize such persons, associations, or corporations to confer degrees, diplomas, or other certificates of qualification in the science of medicine, pharmacy, or dentistry, upon the recommendation of the State board of health, the State board of pharmacy, or the State board of dental examiners, respectively; such revocation to be accompanied by proof that the said persons, associations, or corporations are conducting a fraudulent business or violating the terms of their charters. And provided, further, that this act shall apply to all such persons or corporations which now are or may hereafter be licensed in

this State, notwithstanding any provisions that may exist in their charters.

Women Nurses in the Army.—A women's committee to secure by act of congress the employment of graduate women nurses in the hospital service of the United States army, of which Mrs. Winthrop Cowdin, of New York, is at the head, has prepared the following circular:

"The war of the past summer revealed the need of a larger and better-trained nursing service in the hospitals of the United States army. Since the trained nurse has come to have a distinct professional existence, there had been, until the war, no such need.

"The lack of any sufficiently expansive or regularly organized governmental provision for the work of women nurses gave ample scope for individual effort, and for each and every voluntary organization to serve as best it could. A vast amount of work was done, many soldiers were helped, many lives saved. As a result of practical, intelligent service, these workers reached clearly defined conclusions as to the need of a better nursing service in the army, and the means by which such service can be secured and maintained.

"A number of women thus informed recently called a meeting to consider the results of their experience and observation, and to embody their suggestions in a plan for future action. The outcome of this discussion was the appointment of a committee to secure by act of congress the employment of graduate women nurses in the hospital service of the United States army.

"The committee was chosen to represent the general interest of the home, the philanthropic interest of recent relief associations, and the professional interest of various associations of graduate nurses.

"It now rests with the intelligence of the country to speak through the congress of the United States and to determine whether or not the continuous service of trained women nurses in military hospitals in times of peace and of war shall be authorized by law and provided for by United States statutes, and by army regulations.

"This committee has drafted a bill, now before congress, which embodies the following general provisions, and also many minor details:

"I. The creation of a nursing service commission, military and civil, a part of which shall be women. This commission to have general supervision of the graduate nurses' service of the United States army.

"II. The establishment of a thoroughly graded system of clearly defined and responsible nursing service by graduate nurses.

"III. This service to be responsible to the surgeon-in-chief in hospitals and to a general superintendent of women nurses in the department of war at Washington, and to the surgeon-general and the nursing service commission.

"IV. The bill does not require that women nurses shall be placed in small military hospitals in times of peace, but does provide for their service in hospitals at the larger posts, and for an eligible waiting list of competent nurses who could be called into immediate service in time of emergency.

"V. The general provisions of the bill, and minor detail concerning the administration of the proposed system, are based upon the belief that a military hospital should be conducted on the principles of knowledge and responsibility which prevail in good civil hospitals, adapted, of course, so as to maintain army discipline and military dignity.

"VI. The committee believes that a soldier in the service of the country should receive the same high grade of nursing care, as well as medical treatment, in a military hospital, which the civilian receives in a civil hospital; and that training in no other profession—even though it be a kindred one—can give the necessary knowledge and command of the countless vital details of the work.

"While acknowledging the efficiency of the hospital system in the past, we believe that the advances made in the profession of nursing include and necessitate the presence of women nurses if the best results are to be insured in military as well as in civil hospitals.

"The committee hopes that this bill will meet with your approval and enlist your hearty cooperation and support throughout the entire range of your influence, and that you will write the committee what you can do to help in the passage of the bill, or, in any event, to assure them of your approval.

"Also, we ask you to write to your congressmen and senators at Washington urging them to give earnest and prompt support to the bill entitled A Bill to Authorize and Provide for the Employment of Graduate Women Nurses in the Hospitals of the United States Army. This bill may be passed alone, or may be incorporated as an amendment to the Hull bill. In either case it will be known as The Woman's Nursing Service Bill, and immediate action on your part will greatly help to carry this important measure. It may be that, in the chances to which all legislation is subject, your influence will save the bill."

Recent Changes in Italian Medical Journals.—We learn that *Lo Sperimentale* is hereafter to be published under the title of *Archivio di biologia*, and that its satellite, *La Settimana medica*, becomes autonomous and in some sense a continuation of the *Rivista generale italiana di clinica medica*.

As Glorious if Less Famed!—Dr. Nicholas Senn (*Journal of the American Medical Association*, January 7th), in a response to a toast at the banquet of the Interstate National Guard Association, after describing *Æsculapius* on the field of battle, said:

"Can you give me a more striking example of genuine patriotism and heroism than the twenty-four hours' work performed by our disciple of *Æsculapius* on the field of battle? If you can not, I can. It is the same *Æsculapius* away from the bloody field in the fever camp. It requires courage to face the enemy on the field of battle. It requires courage to stand up in a rain of bullets and in an atmosphere torn asunder every few moments by shot and shell, but it requires more courage to enter the silent fever camp, with its myriads of invisible foes. The song of the bullet is sweet music compared with the silent, invisible microbes that cause yellow fever, typhoid fever, malaria, dysentery, and camp diarrhea.

"It is a privilege to die a glorious death on the battlefield; no such halo of glory surrounds the deathbed in the fever hospital. It is here that the greatest deeds of heroism are witnessed. It is here where the true, manly courage of our *Æsculapian* hero is put to the severest tests. Let me ask you a plain, simple question to test the correctness of the assertions I have made, a question the significance of which, I fear, is not fully understood: If left to choose for yourself, would you not be more willing to engage in a battle

than to live and work in a camp filled with typhoid or yellow-fever patients? It would take me or any other disciple of Esculapius not long to decide in favor of the battlefield."

Hydrogen Peroxide in Puerperal Sepsis.—Dr. John N. Upshur (*Atlanta Medical and Surgical Journal*, December, 1898), in a paper on this subject, says that his method of treatment in these cases is to first irrigate the interior of the uterus with a normal salt solution, remove secundines or other retained foreign materials by means of the sharp curette, and then again irrigate freely with salt solution. After thoroughly drying with aseptic cotton or gauze, hydrogen peroxide is applied to the uterine cavity by means of a small intra-uterine syringe or an applicator upon which is wound a piece of aseptic gauze or absorbent cotton saturated with the agent. The foam should be removed and fresh applications made until the cessation of foaming gives positive evidence that the uterine cavity has been thoroughly cleansed. This procedure should be practised daily until the temperature falls to normal and remains at that point. This, in the author's experience, always occurs within a week. The author then quotes three cases as illustrative of the efficacy of this mode of treatment:

The rationale of the treatment by hydrogen peroxide is, he says, that this agent causes a rapid oxidation or superoxidation of effete organic matter, thus completing in a very short time what it would take unassisted Nature a dangerously long period to accomplish. It initiates, but infinitely improves and accelerates, the efforts of the human organism to remove offending foreign materials. The advantage of this agent over bichloride of mercury, carbolic acid, and other agents that act chemically, is that it is non-corrosive and non-destructive of healthy tissue. Furthermore, the results obtained from the use of hydrogen peroxide are vastly superior to those obtained by the use of any other agent, so that the author now approaches the treatment of puerperal sepsis with less fear of unfortunate results than he has ever before experienced.

The Ocular Evidence of Hysteria.—Dr. Casey A. Wood (*American Journal of the Medical Sciences*, January) concludes his paper on this subject as follows:

"It must not be forgotten that just as hysteria simulates most organic lesions, it may also be present with them. Patriel, has, among others, recently emphasized this important fact, and has reported cases illustrative of it. The eye is no exception to this rule, but fortunately organic alterations in the ocular structures, as examined by the ophthalmoscope, perimeter, etc., usually speak for themselves, and present characters entirely unlike those of a purely functional affection. In conclusion: 1. Most cases of hysteria present well marked, easily detected eye signs and symptoms. 2. A few ocular symptoms, such as reversal of the relation of the color fields and the field for white, the tonic form of blepharospasm, spasm of accommodation and convergence, and pseudo-paralytic ptosis, may be regarded as pathognomonic of hysteria. 3. Defects of vision (in the absence of refractive errors, accommodative anomalies, and fundus lesions), are, generally speaking, hysterical if accompanied by photophobia and any form of blepharospasm. 4. No examination of a patient for hysteria should be regarded as complete without consideration of the condition of his ocular apparatus. 5. When there is no conclusive external evidence of the nervous pro-

ent, the perimeter should be carefully used, the range of accommodation should be noted, and the ophthalmoscope employed. 6. It should always be remembered that ocular hysteria is common in children and men. 7. Organic disease (traumatism especially) of the eye may accompany purely functional disturbances of that organ."

Congenital Deficiency of the Clavicles.—Dr. George Carpenter (*Lancet*, January 7th) records the case of a girl, aged eight years, in whom both clavicles were found, while making a physical examination for another purpose, to be absent. A brother had a similar condition on one side, and the father had a deformity of the clavicle. The following description of the patient's condition is given:

"Examination revealed the following abnormalities: The clavicles were represented by two small fragments, thin, tapering, and cartilaginous (the Röntgen photograph suggests bony as well), attached by their broader extremities to the sternum. The left was longer than the right, their respective lengths being an inch and a quarter and three quarters of an inch. On the index finger being pressed behind the outer extremity of either fragment the fragments could be dislocated so that their direction was nearly straight forward. In this position a depression of the lower part of the sternum was evident and the sternum was seen to be unusually wide at its upper part. As the child stood upright the shoulders were obviously narrowed; they fell downward and forward, the scapular angles projected backward to a marked extent, and under the acromion was seen a depression as in a subglenoid dislocation. What appeared to be the first rib could be felt with great distinctness on either side, as also the coracoid processes. Between each coracoid process and acromion was a well-developed coraco-acromial ligament, and so apparent were these ligaments that they raised the suspicion of acromial clavicular fragments. The sterno-mastoid muscles apparently had some attachments to the fragmentary sternal clavicles. The clavicular portions of the great pectoral muscles were wanting, but the pectoral portions stood out well when placed in action. The anterior portions of the deltoid muscles were also wanting, as also were the clavicular fibres of the trapezius muscles. The child was thin and her muscles were not well developed, but she was not by any means wanting in power. She could carry the youngest child, a well-developed infant a year old, could push and throw well, and could bear the weight of her body when hanging by her hands. She could approximate her shoulders to an extraordinary extent with the greatest ease."

Anomalies in the Course of Innocent and Malignant Growths.—Mr. W. H. Bennett, F.R.C.S. (*Lancet*, January 7th), thus concludes a paper on this subject:

"A careful study of a considerable number of cases, of which those just described in detail may be taken merely as characteristic examples and not as the entire experience, leads me to the following conclusions: 1. That certain tumors, although not necessarily different in structure, pursue an innocent or malignant career spontaneously. 2. That certain tumors, although in structure becoming either innocent or malignant, are of negative malignancy. 3. That the course of an innocent tumor may change to malignant. 4. That malignant tumors may become innocent by the escape of a certain proportion of the cells which are

growth will prove malignant or innocent in its course. 5. That the clinical behavior of new growths is often a better test of malignancy than microscopic examination. 6. That mental concentration on the part of the patient upon the site of the disease is a distinct factor in stimulating the growth of innocent tumors and in the production of malignant disease in certain susceptible subjects. 7. That in nervous subjects of the type described recurrence of malignant disease after operation is more certain and its growth more rapid than in persons of a placid or apathetic disposition. 8. That evidence is wanting to show that operation in cancerous tumors of the breast which have assumed the condition of negative malignancy is, as a rule, necessary or advantageous. 9. That although the practice of candidly announcing to patients suffering from malignant disease the nature of their complaint is, speaking generally, moral and salutary, it may be modified with advantage in patients of the nervous type already indicated.

"In expressing these views I am aware that some of them may be directly opposed to those held by many surgeons. They are, however, deliberately advanced after due consideration. The time at my disposal is only sufficient to enable me to touch the fringe of a subject of considerable magnitude which those who think it worthy of investigation will, I think, find of unusual interest."

The Treatment of Chancroid with Antistreptococcus Serum.—Mr. James Moore, F. R. C. S. (*Indian Medical Record*, December 16, 1898), in a paper reprinted from the *British Medical Journal*, says:

"From my experience with antistreptococcus serum in venereal sores and their complications, I have arrived at the following conclusions: 1. While recognizing the great importance of early local antiseptic treatment of the chancroid, I believe that if five cubic centimetres of the serum are injected subcutaneously into each inguinal region in cases in which inflammatory bubo is likely to develop, it will prove a good prophylactic measure, and assist in healing the chancroid. 2. If inflammatory bubo has already developed, and the acute inflammatory symptoms have not been present more than forty-eight hours, ten cubic centimetres injected into the inguinal region corresponding to the inflamed gland will cause resolution in the majority of cases. 3. If there is evidence of pus formation the serum may possibly limit the extension of the suppuration, but in this class of case my results have been anything but satisfactory. 4. The serum should always be injected into the area drained by the infected gland, preferably the right and left inguinal region. I have not seen good results by injecting it into remote areas. 5. In phagedenic ulceration complicating venereal sores, this serum would appear not only to neutralize the toxins in the blood, but also to bring about a healthy condition of the ulcer."

The Cause of Ankylosis. In our issue for September 21, 1898, we quoted from the *Railway Surgeon* for July 26th the conclusions drawn by Dr. O. W. Phelps from some experiments made by him with a view to determine this question. In regard to Dr. O. W. Phelps' original article, Dr. A. M. Phelps (*Railway Surgeon*, January 10th) refers to a series of experiments in the Leominster Laboratory made by himself in conjunction with Professor W. Gilman Thompson and Dr. J. C. Cardwell. As a result of these experiments they arrived at the following conclusions:

"1. That a normal joint will not become ankylosed by simply immobilizing it for five months. 2. That motion is not necessary to preserve the normal histological character of a joint. 3. That when a healthy joint becomes ankylosed or its normal histological character changed, it is not due to prolonged rest, but to pathological causes. 4. That immobilizing a joint in such a manner as to produce and continue intra-articular pressure will result in destruction of the head of the bone and the socket against which it presses, as is evidenced by specimen No. 1, Figs. 2 and 3, in which there was present the beginning of destructive changes. 5. That atrophy of the muscles of the limb will follow prolonged immobilization of a joint.

"If these experiments prove that prolonged fixation will not produce ankylosis of a normal joint, that motion is not essential for the preservation of its normal function, then the causes of ankylosis must depend upon pathological conditions and not upon prolonged fixation.

"It is claimed that motion in the treatment of inflamed joints prevents ankylosis. If this is a fact, why do the statistics of joints so treated show that ankylosis and deformity, to a greater or less extent, are by far the most frequent result? The statistics published by Shaffer and Lovett in the *New York Medical Journal* show in thirty-nine cases reported on out of a series of many hundred:

Ankylosis	19
Slight motion	6
	<hr/>
	25
Motion from 10° to 44°	7
Motion to right angle	3
Motion free	3

"The three with free motion were treated during the first stage of the disease. Two were under three years old. There were only two cases without shortening. The splint used was the long traction—one which admits of free motion at the hip joint.

"To test this question still further, I sent a patient with knee-joint disease, which I had nearly cured, to a distinguished masseur for treatment by that method. I had perfectly fixed her joint for one year. The apparatus was removed and she had motion to about thirty-five degrees; no pain; could walk easily. She was attended daily by the masseur, and her leg was flexed and systematically moved and rubbed. After six months I found almost complete ankylosis. An examination made last week determined fibrous ankylosis and only a slight degree of motion.

"The 'ossified' man, so called, paid a masseur to move his inflamed joints during two years of his early joint trouble. The result was perfect bony ankylosis of all the joints which were inflamed.

"The fakirs of India, after twenty years of penance, holding their limbs in one position, quickly regain the normal use of their joints after their religious frenzy has passed (Thomas).

"I have several cases of children suffering from joint diseases which have been immobilized in a portable bed ten, twelve, and eighteen months, the joints of the lower extremities being kept perfectly quiet during the time. Recent examinations demonstrated that ankylosis had not taken place in the normal joints, and the inflamed joints are freely movable. I desire to place these cases on record, to stand by the side of those cases of ankylosis reported, supposed to be due to long rest of the joint."

Original Communications.

TYPHO-MALARIAL FEVER, SO CALLED.

By GEORGE DOCK, M. D.,

ANN ARBOR, MICH.
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF MICHIGAN.

THE term typho-malarial fever is in common use in many parts of the United States. It is well known in the South, but is not limited to that section. New York, Pennsylvania, parts of New England, and Ohio may be cited as addicted to the use of the term. In Michigan, it is accepted by the State board of health, and in some parts of the State, even in the northern part, it appears as one of the fifteen diseases most prevalent in some years. In different places and by different men the word is used in various senses, that can be placed in three categories. I intend to discuss these in the order of relative importance, as I estimate it.

The three modes are:

1. To denote a combination of malarial and typhoid fevers.

2. To indicate a malarial fever with symptoms of the typhoid state, or, rarely, a typhoid fever, with intestinal lesions, due to the same cause as malarial fever.

3. Aside from the occasional use of the term to cover obvious diagnostic indolence, to indicate a fever thought by the person using it to be distinct from the typhoid fever of writers, though not necessarily due to malaria.

In the following I mean, by typhoid fever, a disease having certain clinical and anatomical features that are clearly described under that term in all the leading works on medicine. Because these are readily available, I omit a repetition. I also purposely leave out of consideration the aetiology of typhoid fever as not essential to the present discussion.

By malarial fever I mean a disease due to and characterized by the presence of the blood parasites described by Laveran. These fevers have protean clinical features, and can be positively recognized only by the discovery of the specific organisms in the blood of the patient. These statements are not universally accepted by the profession, and therein lies one of the difficulties in the solution of the subject. Often I am told by physicians that they consider the therapeutic test better than the microscopic one, or that they think the finding of the malarial parasite at best corroborative of a clinical diagnosis. Thus, in a recent experience where many physicians were diagnosing diseases of all sorts, neuralgia, diphtheria, jaundice, orchitis, etc., as malarial, my request to have quinine kept off until I had made a blood examination was often met with the answer that I could "have half an hour," and usually in such cases the drug was given, without regard to the blood, in large and repeated doses. It is true the parasites are sometimes few or even absent in the peripheral blood, but such cases are

very rare on the whole. More important is the fact that in a hurried examination the parasites may be overlooked. This is sometimes inevitable in practice, but such cases can not be used to enforce views of classification, nor as models of medical method.

The history of the term typho-malarial fever in sense 1 is very interesting, but can only be alluded to here. A combination of the two diseases was believed to occur by many physicians long ago, especially in the South. The condition was described by Dickson and Drake, and somewhat later (1857) by the late Dr. Austin Flint. To the works of the latter we may go for a statement of the views held by him, as well as by many physicians of to-day.

Flint said (*Practice of Medicine*, fifth edition, 1881): "Remittent fever [the relation of which to malaria he had just described] and typhoid fever may be associated. . . . It has been proposed to employ a name denoting the union of the two affections, and the term *typho-malarial fever* has been introduced by Dr. Joseph J. Woodward. I shall adopt this name," etc. (page 1010). "In typho-malarial fever the symptoms distinctive of the typhoid fever are intermingled with those of periodical fever. . . . In some cases the periodical and in other cases the typhoid phenomena preponderate" (page 1013). "Typho-malarial fever is not a distinct type of fever. It is, however, of great importance to recognize the combination of typhoid and malarial fever" (page 1014). The importance here alluded to is no doubt the following: "In typho-malarial fever the periodic element claims the treatment indicated in simple remittent fever. The object is to eliminate this element by means of antiperiodical remedies. Aside from this object, the hygienic and medicinal measures indicated are the same as in cases of unmixed typhoid fever" (page 1016).

As Flint said, the term typho-malarial fever was originated by Woodward. It became well known very rapidly in the civil war through the work of that author, *Camp Diseases*, and filled a want in substituting what seemed a scientific term for such names as "Chickahominy fever," then in use. In 1876, Woodward read a paper on typho-malarial fever at the International Medical Congress in Philadelphia. This did much toward clearing up certain errors attributed to the author, but had a very slight effect on the attitude of the profession to the disease. Woodward did not live to write the chapters on typhoid and malarial fevers in the *Medical and Surgical History of the War of the Rebellion*. Perhaps, with his industry in such matters, he would have been able to make a strong case for the term. As it is, the author of the third medical volume could find in the records only three clear illustrations of cases diagnosed typho-malarial fever. One of these, the writer says, shows no evidence of malaria on critical examination.

We must bear in mind, in studying this subject, a great but unavoidable error entertained by the older writers. Though no longer unavoidable, the error is still held by most of those who at the present time make the diagnosis of typho-malarial fever. The error is this, that from the symptoms of the disease one can conclude its double origin, or, as the older writers would say, its hybrid nature. Down to a time more recent than Woodward's latest utterance on the question, we had little knowledge of the pathology and morbid anatomy of either typhoid or malarial fever. Woodward's knowledge was meagre with the rest, as his book *Camp Diseases* shows. Larger experience with autopsy specimens led him to abandon his early view that there was something specific in the intestinal lesions of typho-malarial fever, and admit their identity with those of uncomplicated typhoid fever. His clinical experience, however, had no similar control, and like most people with insufficient anatomical knowledge he placed too much reliance on symptoms. Thus, after saying that the "big spleens, pigmentary deposits, and other anatomical evidences of malarial complications were of uncertain diagnostic value," he continued: "I can not but see in the periodicity and other clinical evidences of malarial complications proofs of the action of an additional morbid agency, to which I doubt not we must look for one reason of the great mortality of the fever cases in the army." The "other clinical evidences of malarial complications" are mentioned more specifically in the same place as "gastric and hepatic disturbances and ague paroxysms in the convalescence."* In *Camp Diseases* (page 87) they are spoken of as follows: "Tendency to periodicity, icteroid hue, enlarged spleen, tender liver, and gastric disturbance." Of course these statements simply beg the question, but neither Woodward nor his followers seemed to realize the fact, and so it appears necessary to offer a brief criticism.

Down to a recent time periodicity was universally looked on as presumptive evidence of malaria, and even the important work of Murchison, Musser, and many others has not eradicated this idea. It is, in fact, a common occurrence, when one asks why certain cases in practice are called malarial, to be told, "Because of their malarial characteristics," and if one asks for a more definite answer, one is told either that the patient gave a history of chills at some time, or that the temperature has shown great variations.

Now we know that periodicity of great regularity can occur without any malaria, and without any exposure to it. Many illustrations have been published in the last twenty years, and I have communicated some striking examples.⁴ On the other hand, a malarial

fever may be quite irregular in its course, as is also well known. Moreover, periodicity is often claimed without sufficient proof. Patients often say they have had certain periodic fevers which accurate temperature records show to be not at all periodic. So far as the experience of the civil war is concerned, it is often forgotten that the clinical thermometer was not then in use. Any one who has taken temperatures in fever cases knows how unreliable the sensations of the patient and the hand of the physician or nurse may be. Even when the thermometer is used, but at long intervals, the record may be very misleading.

It has long been known that chills may occur in typhoid fever in any stage. Their occurrence in the early stage was noted in some of the earliest descriptions of typhoid fever as a distinct disease, such as those of Louis, Bartlett, and Jenner. Bartlett was aware of the combination of malarial and typhoid fever, so that when he said (*History, Diagnosis, and Treatment of the Fevers of the United States*, second edition, p. 41): "Like most acute diseases, typhoid fever is attended by chills or rigors," we can hardly think he was dealing with mixed cases. In London, also, where in a "typical case" of typhoid fever mentioned by Jenner the patient had rigors on four successive nights in the beginning, a malarial element may reasonably be excluded. So, down to the most recent writers on the subject, we find warnings in regard to the danger of mistaking cases of early typhoid with chills for malarial fever.

In the second stage of typhoid fever chills are not so common as remissions, but both may occur, independently of all malarial influence. The contribution made to this topic by Osler (*Johns Hopkins Hospital Reports*, Part V) is one that should be read by all interested in the study of typhoid fever. I have found both chills and remissions most frequently in the second stage in cases treated by large doses of antipyretics, including the popular quinine and salol, but I have also seen them in uncomplicated cases treated only by the cold bath. (I of course am speaking of the symptoms not due to the bath.) Sepsis should always be searched for in such cases. In one of mine it was brought on by multiple small skin abscesses.

Chills in the defervescence and convalescence are also not uncommon, especially when antipyretics are given, as is often the case in private practice, to make an impression on a stubborn temperature, and the chills and sweats after such treatment often cause more alarm than the symptom it was given for. It is good practice to assume that chills in the later stages of typhoid fever are due to any other cause than malaria, and to look for the cause. Phlebitis and thrombosis are often introduced by chills and fever. I have seen a pure tertian intermittent, with three paroxysms, in the onset of fem-

* *Transactions of the International Medical Congress, Philadelphia, 1876*, p. 332.

⁴ Endocarditis and Intermittent Fever, *Boston Medical and Surgical Journal*, November 7, 1895; Staphylococcus aureus Infection with En-

docarditis simulating Malarial Intermittent Fever, *New York Medical Journal*, January 30, 1897.

oral phlebitis, without evidences of malaria. (The infection originated in northern Michigan, the phlebitis appeared late in convalescence in Ann Arbor.)

Woodward's other evidences of malaria are even less convincing than periodicity and chills. The icteroid hue has been extremely rare in the numerous cases of so-called typho-malarial fever I have seen in the North, as it was among the several hundred cases so diagnosed I saw in army hospitals. Jaundice, usually of more than moderate intensity, was observed in a number of cases as a complication, but none of these cases had evidences of malaria. In the South a sallow tint is not uncommon, and is to be expected there in typhoid fever without regard to malaria, in some cases. The patients I saw in the camps were largely from the North, and I made particular efforts to observe in them an icteroid hue as a control on the symptom of yellow palms, described by Filipowicz (*Centralblatt für die med. Wiss.*, No. 11, 1898). (I may add that yellow palms were present only in a small proportion of cases, but in some were very striking.)

Enlarged spleen—that is, palpable spleen—may be absent in malarial fever, and probably is, in mild cases, as often as in typhoid fever. In general the organ is larger in the former disease, but it is sometimes very large in uncomplicated typhoid fever. One that I removed at Sternberg Hospital from a patient who died on the tenth day was eight inches long, and estimated to weigh one pound and a quarter. There was no gross or microscopic evidence of malaria. The mesenteric glands were unusually large. Typhoid bacilli were cultivated from the spleen by my colleague Dr. Charles F. Craig.

The tender liver of Woodward is also very uncertain as a diagnostic factor, since it is often absent in malaria.

Gastric disturbance (speaking of symptoms) is rare in typhoid fever, and has been rare in most of the cases of so-called typho-malarial fever that I have seen in private practice and in patients admitted to my wards with that diagnosis. But even in uncomplicated typhoid fever, in the North, there are exceptions, and in a recent case in the University Hospital, a mild one with Vidal's reaction and no malarial organisms, there was vomiting in the beginning and there was a tendency to nausea almost constantly up to defervescence. Two things are very likely to cause gastric disturbance—overmedication and faulty diet. Both of these were common in army camps during the recent war, and no doubt also in the civil war. Patients who were kept in quarters, as often happened in some regiments, until they were in the typhoid state, with nothing to eat but the badly cooked army rations, were pretty sure to have irritable stomachs, and those who took the usual doses of quinine, six to ten grains four times a day, also often had gastric complications, up to intractable vomiting.

So the proofs relied upon by Woodward are insufficient. But claims such as he advanced are antecedently

untenable in the light of present knowledge. When Woodward spoke of a hybrid disease he meant a blending of symptoms; but symptoms no longer suffice for classification. In accordance with more modern ideas, such cases as he described are often spoken of as combined infections, but too often without adequate proof of the combination. The proofs are the demonstration of the malarial parasites in the blood, along with evidence, as full as our knowledge permits, of the coexistence of typhoid fever. Eight years ago, in a paper on the Fevers of the South (*Medical and Surgical Reporter*, January 24, 1891), I admitted the existence of combined typhoid and malarial infection, basing my belief on general principles there detailed, and on the cases reported a short time before by Dr. J. J. Kinyoun (*Abstract of Sanitary Reports*, April 11, 1890). (As I have remarked elsewhere, Kinyoun's conclusions are not all convincing, but that he early recognized the combined infection can hardly be doubted.) I went on in the address mentioned: "The question now (1890) is, not whether there is such a combination, but when, where, and under what aspects it appears." I was quite unprejudiced, although my experience, as I then said, had made me look with great skepticism on the current reports. Since then much has been written on the subject, most of the articles, unfortunately, being controversial rather than objective. I have in the meantime made many examinations in suspected cases, but so far have failed to find a case of mixed typhoid and malarial infection. Many of my cases were pronounced typho-malarial fever by physicians of high standing, authors of note on the subject, and convinced of the soundness of their view. In a number of cases autopsies were made, but without revealing a latent malaria. This experience was obtained partly in Texas, partly in Michigan, and more recently in army hospitals in Chickamauga Park, Georgia; Knoxville, Tennessee; and Camp Meade, Pennsylvania. In the latter hospitals I made many blood examinations on patients in cases diagnosed as typho-malarial fever, who still presented the symptoms on which the diagnoses were made, but without success. As a matter of fact, I was able altogether to find only two cases of malarial infection in the camps, and both the patients recovered promptly under relatively small doses of quinine. (No fever after one day's treatment in each case. Both cases were *residues* of malarial disease acquired elsewhere.)

Since knowledge of the blood parasite has become widespread thousands of cases of malarial fever have been carefully studied. Hundreds of cases of typhoid fever have been searched for the malarial parasites, but only a few cases have been reported in which there was a combined infection, and these do not go far toward showing a peculiarity in the clinical picture. Kinyoun said he had observed in the few cases he saw such characteristics as Woodward described, but his report of the cases is too brief to bring conviction to others.

In a case of W. Gilman Thompson's (*Transactions of the Association of American Physicians*, 1894) the parasites were found in the third week of typhoid fever. The temperature was remittent, and there were chills, but it can not be said the case differed much from other cases of typhoid in which malaria could be excluded. Jane-way, in the discussion of Thompson's paper, mentioned a case in which he found the lesions of both diseases, but expressly stated there were no phenomena of malaria. No more painstaking and extensive observations have been made in this field than those of the Johns Hopkins Hospital. Yet Osler, Thayer, and Hewetson found no concurrence of the two diseases, and in typhoid fever following closely after malarial fever they could see no reason for believing in the existence of a hybrid. Laveran's extensive experience has been that neither intercurrent malarial infection in typhoid fever nor typhoid fever following malarial fever has peculiar features. His statement that remissions are not more marked in malarial remittent than in typhoid fever deserves investigations in the typhoid fever of non-malarial localities. On the other hand, the cases of Vincent,* in Algiers, seem to have shown certain peculiarities. The author looks on an earthy tint and an enlarged spleen as diagnostic features of the combined infection, but such cases seem to have formed but a small proportion of all the fevers he encountered.

In concluding the consideration of the first variety of cases called typho-malarial, we find that the belief in a characteristic disease composed of typhoid and malarial elements is not based on sufficient evidence; also, the idea that the two diseases named are frequently associated remains to be proved.

Material in abundance is available all over the country, and it is unfortunate and not creditable to the modern spirit of investigation that so little work is done on it. As I remarked in my report to the surgeon-general of the army, the recent mobilization of troops furnished an interesting field. With large numbers of cases of typhoid fever from all parts of the country, the combination with malaria was certain to occur. The field hospitals were unfavorable for its detection, on account of the universal use of quinine, and the most accurate observations must, therefore, be expected from city hospitals where cases were studied with regard to the questions involved.

While awaiting the results of such investigations, it may be worth mention that a tendency to inaccurate use of the term "mixed infection" seems about to replace the "typho-malarial fever" of the recent past. If malaria is demonstrated before or after a typhoid fever, but not in it, there is no more reason to speak of a mixed infection than there would, in any simple case of pneumonia, to speak of a mixed infection because streptococci were found in the mouth. Enough cases have been

reported to show that malarial organisms may remain latent in the body even during the course of typhoid fever, just as pus germs may.*

Adynamic Malarial Fever, or Typho-malarial Fever of Class II.—The idea of a malarial fever becoming typhoid is old, but changes its expression from time to time. The older writers made no sharp distinction between adynamic conditions and typhoid fever. Even Woodward was in this class, as appears from the following: "The ordinary remittent fever under this influence—i. e., adynamic tendency—assumes a new character, presenting from its very earliest stages a typhoid tendency, which masks to a great extent its real character, and justifies fully the new designation of typho-malarial applied to such cases in this volume."† Woodward was apparently unaware of the difference between such cases and those he discussed more fully in the volume mentioned, and in the International Congress of 1876. Flint admitted the possibility of the typhoid state in remittent malarial fever, and distinguished it from the combination of typhoid and malarial fevers. Besides this view, there exists even now a belief that malarial fever can show not only the symptoms of the typhoid state, but also the lesions of typhoid fever, without typhoid infection. This idea one can hear elaborated in meetings of medical societies, and from more than one army surgeon I have heard explained how the ulcers, mesenteric-gland enlargement, etc., in ordinary cases of typhoid fever, were due to "malnutrition," "asthenia," "depraved nerve supply," etc., from chronic malarial poisoning. This view does not seem to deserve further discussion.

That the typhoid state can occur in malarial fever does not admit of argument, but after considerable study in cases so diagnosed, finding them all typhoid, and after extensive discussion with practitioners in malarial localities, I must reiterate that the condition described must be very rare, and must usually be due to extraordinary combinations of neglect and improper treatment. I have recently seen a case showing how much a malarial patient can stand, and although I do not wish to seem to oppose it to a positive example of the other class, a brief recital may be interesting:

P. A. W., a young volunteer from Michigan, had malarial fever at Santiago in the end of July, becoming semicomatose for three or four days. The fever returned at Camp Wikoff in the end of August. After that there were "dumb chills" every other day for about a month, and all through October there were ague paroxysms almost daily. The chill lasted about an

* Since I wrote this paper a valuable discussion on some experiences with army cases has appeared (*New York Medical Journal*, November 19, 1895). It does not become probable from this that a malarial infection produces any characteristic change in the type of typhoid fever. On the other hand, the fact was brought out, as Laveran has already shown, that the evolution of the hematozoa sometimes seems to be checked by the onset of typhoid fever.

† *Camp Diseases*, p. 10.

* *Le Mercey Medical*, December 1, 1895.

hour, the fever two hours or more, followed by moderate sweating. There were three or four loose stools a day, the result of a diarrhoea contracted at Camp Alger early in June. The patient lived on light diet, such as oatmeal, eggs, baked apples, and figs. For two months he was under treatment by a homeopathist, who told him it was dangerous to stop the chills. I saw the patient on November 1st. He was very pale and weak, but had not taken to bed. The tongue was pale, thin, and broad, without a coating. The spleen extended three finger-breadths below the costal margin, and was hard and painful; the liver, also three finger-breadths below the ribs, in the nipple line, was not painful; no tenderness in the epigastrium or right iliac fossa. The blood was thin and watery, and showed an increase of leucocytes. It contained a few parasites of the tertian form, with typical segmenting bodies at the third examination, just before a chill. There were large numbers of very small endoglobular bodies, with almost invisible pigment grains. During the five hours the blood was examined, these did not become larger than one fourth the diameter of the red corpuscles. Most of them were in the seal-ring stage. Pigment-bearing leucocytes were rather numerous; the pigment in small black blocks. The small parasites were so numerous that two or three could usually be found in every field of the one-twelfth-inch lens. The blood was examined fresh and in dry preparations. Here was evidently a man in whom a severe malarial infection lasted two months, with other depressing conditions, yet there was no indication of a typhoid tendency. Forty grains of quinine, in two doses, in the first twenty-four hours after making the diagnosis stopped the paroxysms, which have not returned in the three weeks the patient remained under observation. The organisms were present for three days. Ten grains of quinine were given at one dose every five days after the last paroxysm.

Scattered through recent medical literature are accounts of cases called malarial, running a protracted course, or even said to closely resemble typhoid fever, and not yielding to quinine. In some of these the malarial organisms were not searched for; in some they were said to be present, but the descriptions given lead us to suspect the observers were without sufficient experience. I have known a surgeon of high rank in the volunteer army who professed to make microscopical diagnoses of malaria, although he was unable to distinguish between red and white corpuscles in fresh or stained blood, and ignorant of the most elementary microscopic manipulations.

Investigations on the malarial parasites have revealed numerous cases of malarial fever beginning like typhoid fever, and in all that I know, unless there were complications, such as other infections, or inflammation of organs, the symptoms stopped within a very few days, usually less than four, after the administration of quinine was begun. The only example of malaria I saw in Sternberg Hospital was diagnosed as typhoid fever by the surgeon in charge, a Southern physician, and accustomed to see both diseases at home. The temperature curve and the symptoms certainly suggested typhoid; it was too early to lay much stress on the nega-

tive Widal reaction. The temperature, however, previously as high as 105.5°, fell at once after giving eighteen grains of quinine, and with it all the other symptoms except anæmia disappeared. The blood showed a double tertian infection of moderate intensity; the organisms definitely disappeared three days after the treatment mentioned, and did not reappear during the subsequent ten days of observation.

My conclusion as to this part of the subject is that an uncomplicated malarial fever resembling typhoid, lasting more than a few days and uninfluenced by quinine properly given, is rare. There are few exceptions to the statement of Osler, that any fever not checked in five days by quinine is not malarial. My own opinion, shared by many experienced physicians, is that five days are not often necessary, three being usually enough to break up a malarial fever, even in the South. If there are well-authenticated cases that contradict this belief, publication of the details would be very useful. In the meantime, such assertions as the following from an anonymous review of Dr. Thayer's book on malaria may be good prophecy, but can not be accepted as evidence: "The term typho-malarial fever is likely to persist as the designation for the low, asthenic fever due to paludism frequently seen in the Mississippi Valley."

The third sense in which the term typho-malarial fever is used is not often encountered. When it is, it is usually easy to discover that no deep-seated belief exists as to the malarial nature of the disease. The term is often used as a refuge in diagnostic doubt or difficulty, often to avoid an admission of the existence of typhoid fever. In this sense it is common in summer resorts in the North. For such reasons, boards of health often require notification as in the case of typhoid fever, and then such names as "catarrhal fever," "gastric fever," or local terms are likely to be used. Very often we find, with such habits, an actual ignorance of the symptomatology of typhoid fever. A regimental surgeon in the late war is said never to take the temperature unless the pulse is over 120, calling everything with hot skin and pulse less frequent than 120 malarial fever. This ignorance of one of the most important features of typhoid fever is remarkably common. As a contrast to this state of affairs, the typhoid state is taken without further question as evidence of typhoid fever, and so we see pneumonia, tuberculosis, sepsis, and the terminal infections of all sorts of organ diseases called typhoid fever by those who give some other name to the latter disease.

In general it may be accepted as a fact that out of a large number of cases of fever called by names not used in ordinary text books, the majority will prove to be typhoid fever. Some may be infections of other kinds, or intoxications of various sorts, but the effort sometimes made to explain them all by the current terms "auto-infection," "uræcædemia," etc., can not stand the test of post mortem examination.

A curious phase of the discussion of typho-malarial fever centres around the severity of the disease. It is often said that a given case or epidemic can not be typhoid fever alone, on account of the alleged mildness of the symptoms. Especially in the South is it maintained that the common protracted fevers can not be typhoid, because of their mildness. So far as my own experience is concerned, I have seen typhoid fever in Texas quite as severe as some of the most serious I have encountered in the North, and I know no statistics large enough, and otherwise trustworthy, to support the assertion of special mildness in the South. I was especially struck by the importance of the personal equation on this question when at Chickamauga, where the typhoid-fever cases reminded me vividly of old experiences in Kensington, Philadelphia, and of the cases treated on the expectant plan in certain German hospitals. I was speaking about these cases with an experienced trained nurse familiar with the disease in New York and Boston, when she said: "This is not typhoid fever. That never has such depression and delirium, such bad tongues and dirty mouths (some had maggots in them on admission), such bed-sores and abscesses." I was reminded of a discussion I once heard in a medical society in the far South. The health officer, who denied the existence of typhoid fever in the town, closed his argument with the following appeal: "Where do you see, in these cases, the dry, cracked, and bleeding tongue, and the flies crawling on the cornea, as in typhoid fever?"

This matter is not a mere discussion about a name. It involves important questions of diagnosis and treatment. Until the careful examination of the patient becomes the rule, and he is treated for his actual condition rather than for the name of his disease, serious errors can best be avoided by discouraging slipshod terminology, as exemplified by the current use of "typho-malarial fever." Often I have known patients to be told they had typho-malarial fever, and advised to eat and walk all they could, "in order to keep up their strength." In one case the patient followed this advice up to the beginning of the fourth week, and almost at the time his physician was trying to prove to me the man had a hybrid fever, not described by teachers of medicine, and certainly not typhoid fever, the patient was having a hæmorrhage which shortly preceded his death from that disease.

A malarial complication in typhoid fever should be recognized if present, like any other complication, and it can be recognized positively only by the blood examination. When found, it should be treated as Flint so tersely explained. If malaria is suspected, but the microscopical examination can not be made, a therapeutic test may be tried, but the method and limitations of this must be clearly understood. It will not remove the fever if the malarial is associated with typhoid fever, so that when the microscope is not used it is necessary to use the quinine with great care, giving neither too

much nor too little, and not keeping up the drug for more than two or three days at a time.

In a case resembling typhoid fever, but really malarial, the microscope is essential to good practice. Without it, quinine may again be used; but if the temperature does not fall to or near normal, with relief to the other symptoms, it is better to stop the quinine altogether. Only when microscopical evidence of malaria is present should the drug be pushed after the third day. It is necessary to add that while symptoms persist the patient should be treated as though he had typhoid fever. So erroneously is the so-called therapeutic test conceived that I have known of patients taking quinine in doses of forty grains a day for three weeks, in order to determine the presence of malaria, each fall of one or two degrees of temperature being looked on as proof of a specific effect. I am well aware that some look on massive doses of quinine as useful in typhoid fever, but considerable observation has convinced me of the opposite view.

As an instructive example of the sort of treatment Flint did not advise, I append the brief history of a case as given me by one of the physicians concerned. The story as I got it had all the brutal candor of truth, and I think I have the essential points:

A prominent man had symptoms of a fever, and a diagnosis of malaria was made. Antiperiodic treatment was carried out for a week without improvement. Treatment was continued, and a specimen of blood was sent to a distant city, in order to have it examined for the Widal reaction, as the symptoms were becoming suspiciously like those of typhoid fever. As the result was negative, the treatment was continued. Another blood preparation gave a similar report, and as the patient was now becoming notably weaker he was sent a considerable distance to the mountains, in order "to drive the malaria out of his system." A specimen of blood at the end of the third week brought the answer: "Suspicious; send another preparation." This was sent, but by the time the answer came, this time positive, the patient was dead.

Such cases as this, and they are by no means rare, show the harm that is likely to be associated with any form of specific treatment, and especially in a disease with so many possibilities in the way of complications as typhoid fever.

TORSION OF THE PEDICLE OF AN OVARIAN TUMOR.*

By PAUL F. MUNDÉ, M.D., LL.D.,
GYNÆCOLOGIST TO MOUNT SINAI HOSPITAL;
CONSULTING GYNÆCOLOGIST TO ST. ELIZABETH'S, THE SKIN AND CANCER,
AND THE MOTHERS' AND BABIES' HOSPITALS;
CONSULTING OBSTETRICIAN TO THE CITY MATERNITY HOSPITAL.

ADHESIONS to the parietal and visceral peritonæum—that is, to the abdominal wall, to Douglas's pouch, to the omentum, intestines, and bladder—are the most fre-

* Read before the Section in Obstetrics and Gynecology of the New York Academy of Medicine, January 26, 1899.

quent complications of ovarian tumors. More rare are inflammation and suppuration of the tumor, and still more unusual, bursting of the cyst and evacuation of more or less of its contents (accordingly as the cyst is a monocyte or a polycyst, only one of the compartments of which bursts) into the peritoneal cavity, and the usually resulting peritonitis. Between these two conditions lies the accident which is the subject of this paper—namely, the twisting of the pedicle of the tumor, which presents one of the most curious and interesting features encountered in the development and pathology of ovarian tumors. This phenomenon was first reported by Hardy, of England, in 1845; then by Ribbentropp, of Germany, in 1846; and next by Van Buren, of New York, in 1850, the tumor in the last case being a solid ovarian. Since then numerous observations of this peculiar occurrence have been recorded, mostly by ovariologists, although Rokitsky has published a number of interesting cases first discovered on the post-mortem table in his text-book and in an article in the *Wiener allgemeine Med.-Zeitung*, 1860. A succinct article on the subject from personal extended experience has not, to my knowledge, been written outside of the comparatively brief review of the topic in gynecological text-books.

The pedicle connecting the ovary with the uterus consists of the broad ligament, Fallopian tube, and ovarian ligament, and is usually not more than two inches long and an eighth to a quarter of an inch thick. The larger the tumor, especially if it is a polycyst with thick, viscid or colloid contents, the thicker the pedicle is likely to be, and therefore, even if rather long, the less likely to become twisted. And if the tumor has attained so large a size as to more or less fill the lower portion of the abdominal cavity and to be compressed by its walls, there is then little danger of its being turned on its axis and of its pedicle becoming twisted.

The Fallopian tube is not always included in the twist, which may be directed inward, toward the uterus, or the reverse.

Torsion of the pedicle may thus safely be said to occur and be possible only when the tumor is small and still freely movable in the abdominal cavity.

Two conditions are therefore essential to the production of a torsion of the pedicle of an ovarian tumor: 1. A long, slender pedicle. 2. A small tumor, not larger than a fist, or at most a cocoon. The size of the tumor when removed does not indicate its size when the torsion occurred, for it has grown with each twist.

Further, the tumor must be in the abdominal cavity, for the freedom of motion necessary to torsion of the pedicle is not present when the tumor lies in the pelvic cavity, as is often the case when it is still so small as to find room in its usual location behind the uterus in Douglas's pouch.

What particular agencies are to blame for the rotation of an ovarian tumor is not definitely known. Most

likely the peristaltic movements of the intestines and their frequent gaseous distention play a prominent part in the axis-rotation of the tumor, and probably accidental jars and shocks or a lateral recumbent position of the woman assist in the process.

The irregular shape of multilocular tumors of the ovary; the lateral inclination given to an intrapelvic ovarian tumor as its growth forces it past the sacral promontory out of the pelvic cavity; and the displacement of the tumor by the gradual growth of a pregnant or fibroid uterus, or the sudden emptying of a pregnant uterus, are other factors possibly chargeable with this accident.

In one case of a doubtful abdominal tumor extending from the left hypochondrium to the right iliac region, with sharp inner border and fairly firm consistence, resembling somewhat a malarial or leucoerythemic spleen, while manipulating the tumor at my office, for the purpose of determining its nature, it suddenly slipped from my fingers and made a partial twist. The patient complained of sharp pain and nausea, went home in a carriage, and took to her bed with a quite severe attack of peritonitis. After a week, when the acute symptoms had somewhat subsided, I operated and found a polycyst of the ovary with a single twist of its pedicle, undoubtedly inaugurated by my manipulations. At present I would operate at once without waiting for the acute symptoms to subside. Removal of the tumor would be the best means of relieving the inflammation.

An untwisting of the pedicle may be produced by a reversal of the agencies which caused the torsion, but I have never seen this occur.

The torsion may be either gradual or sudden, either partial or total. The pedicle may be twisted once on itself or several times, until it has become so thin as to appear on the point of breaking. In accordance with the number and tightness of the twists the circulation of the tumor is more or less interfered with, and an acute serous exudation takes place into the cyst, if the tumor is cystic, or the effusion may be bloody, or the walls of the cyst or the mass of the tumor may become oedematous or infiltrated with blood.

As a result of this interference with the blood supply to the tumor and the resulting edema, apoplexy, and serous exudation, the tumor undergoes a rapid increase in size, and the color of its walls changes from a pearl-gray to brown or black. Usually but one twist takes place at a time, each attack being attended by more or less acute pain on the affected side of the sub-umbilical region, by possible faintness and collapse, by moderate distention and tenderness of the abdomen, and by some increase of pulse and temperature. The symptoms are not unlike those of an acute attack of appendicitis, especially when reflex peritoneal irritation, as shown by bilious vomiting, is present, and the pain and distention happen to be on the right side. An error in diagnosis has been made in this respect even

by experienced practitioners, and the error has not been discovered until the abdomen was opened by the usual lateral appendicitis incision.

Ovarian tumors are ordinarily not painful, even on pressure, unless complicated by adhesions or inflammation. Hence, when an ovarian tumor is met with which is of small size, movable and painless on pressure, and which suddenly increases in size, becomes tender to the touch, and loses its former mobility, the suspicion of acute congestion or inflammation of the tumor is justified, and the assumption that the change is due to a torsion of its pedicle is warranted. No other causes known to me are likely to produce such phenomena in an ovarian tumor.

Only small dermoid tumors of the ovary, the pedicle of which is equally liable to torsion,* at times become inflamed and undergo suppuration, probably in consequence of their greater vascularity and susceptibility to bruising, such as may occur during coition, parturition, or the passage of hard scybala, when the tumor is intrapelvic.

Torsion of the pedicle of an ovarian tumor may occur on either side, but scarcely on both sides if there happen to be two ovarian tumors at the same time, as often occurs. This is easily explained, for there may be ample room for one ovarian tumor to rotate, but not for two. At least I have never seen two twisted pedicles at the same time in the many cases of double ovarian tumors on which I have operated.

A curious feature is that often the tumor lies on the side of the abdomen opposite to that from which it sprang. This is explained by the natural impulse given the tumor during the process of rotation; once on the opposite side, its rapid increase in size keeps it there, as well as the adhesions which the inflamed tumor forms to the neighboring organs. The direction of the torsion in such cases is inward toward the uterus.

The *first* result of the torsion, as already stated, is the greater or lesser interference with the circulation and nutrition of the tumor; the *second*, its increase in size from serous or bloody exudation, or from apoplexy into its walls; the *third*, adhesions to omentum, abdominal wall, intestines, or bladder; the *fourth*, gangrene and rupture of the sac, if the tumor is cystic, provided the adhesions do not save the tumor from this fate by supplying the nutrition which has been cut off through its natural channel, the pedicle; the *fifth*, chronic peritonitis, with turbid serous exudation; or, if the gangrenous cyst actually ruptures, acute septic peritonitis and death.

* Of Hsu-en says that dermoid ovarian tumors are particularly liable to torsion of the pedicle, with which assertion my experience agrees. Of thirty-five ovarian dermoids removed by me there were eight with twisted pedicle, or about twenty four per cent. — that is, about four times the proportion of torsion in ordinary ovarian tumors. The reason for this preponderance of dermoid is that they seldom grow to a large size, and, being more or less solid, are more easily rotated than cystic tumors.

During this course of events, unless the tumor is removed in time, the patient is subject to the peculiar toxic effect of ovarian tumors, known as "ovarian cachexia," and to the dangers of resulting chronic peritonitis and ascites with septic temperature and pulse, the former ranging up to 103° and the latter to 120, neither, however, indicating the true gravity of the situation.

The fifth result—rupture of the gangrenous cyst, general septic peritonitis, and death—is fortunately a rare occurrence, the adhesions, which inevitably form if time is given, being usually adequate to the imperfect nutrition of the tumor so as to save it from absolute death.

It is surprising how disorganized such a tumor may become, until it is black in color, and so soft and friable as to break on the slightest touch, and still be preserved from actual putrescence by adhesions.

To this provision is due the comparatively low mortality from this accident, which in our day of early and relatively safe ovariectomy is not allowed to progress undiscovered and unrelieved to its otherwise inevitably fatal termination.

From what has been said it may be inferred that the symptoms produced by the torsion of the pedicle of an ovarian tumor differ in accordance with the rapidity and tightness of the twist, and the number of the attack. If the torsion has been sudden and complete, the symptoms are sharp and acute, and the general distress great. If, on the other hand, the twist is gradual and loose, there may be comparatively little disturbance for a time, and it requires a tightening of the twist or one or more additional rotations of the tumor before the abdominal distention, pain, fever, and general constitutional depression induce the patient to consult a physician. Thus this condition may produce sudden alarming symptoms, or may exist almost unnoticed for weeks and months.

Intestinal obstruction may take place when the gut is adherent to the twisted tumor and becomes rotated on its own axis or sharply flexed in consequence, or when the pedicle of the tumor happens to catch a loop of intestine in its rotations. Fatal cases of this kind have been reported by Hardy, Ribbentropp, and Rokitsansky.

A result of pedicle-torsion which I have never witnessed, but which is mentioned in literature, is the shriveling of the cyst with inspissation of its contents, or fatty or calcareous degeneration of its wall, produced by the gradual shutting off of its blood supply. In such cases the torsion must have taken place gradually and not with such rapidity and thoroughness as occurs in those cases where acute inflammation and gangrene of the tumor ensue.

I have no data as to the mortality from twisted pedicle when not cured by removal of the tumor. I doubt if any such data exist. But I have recorded only

two deaths from twenty-nine operations for twisted pedicle, both from pre-existing septic peritonitis, the cases having been neglected too long before coming under my observation.

Barnes reports two cases of death from septic peritonitis due to twisted ovarian pedicle, occurring during pregnancy, and Moeller one three days after confinement from the same cause. But these are old records, and doubtless there are others in recent literature.

As regards the frequency of twisted pedicle, I have met with twenty-nine instances in four hundred and thirty-eight abdominal sections for ovarian disease, or about six per cent.

As the large majority of ovarian tumors are cystic, single or multilocular, naturally it is usually a torsion of the pedicle of an ovarian cyst with which we meet; but there is no reason why a solid tumor of the ovary might not, under similar favoring conditions, meet with a like fate.

Indeed, there are cases on record where a fibroid connected with the uterus by a long, thin pedicle has become inflamed through torsion of its pedicle and has at last been entirely detached from the uterus and nourished through adhesions. The uterus itself has been so much elongated by the upward growth of a fibrous tumor springing from its upper portion that a torsion of the organ at its naturally slenderest part at the internal os has taken place.

Other tumors attached to the uterus by the same tissues composing the ovarian pedicle may be subjected to rotation and pedicle-torsion. For instance, I have operated in one case of parovarian cyst with twisted pedicle, and in another of ruptured ectopic pregnancy with the same complication. In the latter case the torsion must have occurred before the rupture.

Instances of this kind are undoubtedly rare.

The *diagnosis* of a twisted ovarian pedicle has already been referred to. I will briefly recapitulate its salient features: A moderate distention of the subumbilical region, with greater prominence either in the median line or on either side; rapid formation of the swelling, which perhaps was merely noticed before; more or less tenderness on pressure; tense but distinct fluctuation, with single or interrupted wave accordingly as cyst is single or multilocular; outline of swelling generally distinct, but sometimes diffused; dullness on percussion over area of swelling; tumor touchable through anterior vaginal vault, and continuous with suprapubic swelling; uterus generally posterior to vaginal swelling; fluctuation-wave in vagina continuous with abdominal wave; temperature somewhat elevated, perhaps to 102° ; pulse rapid and small; general depression; anxious countenance. The attack has usually come on suddenly, and may have been preceded at an interval of several weeks or months by a similar less marked seizure attended by severe pain.

If several twists are found on operation, each twist

was probably signalized by an acute attack. If a woman known to have a small ovarian tumor experiences symptoms such as the above-described, the presumptive diagnosis of torsion of the pedicle is justified.

In one of my cases of twisted pedicle the symptoms were those of rapid formation of a movable, hard, nodular tumor in the right middle part of the abdomen, with cachexia and emaciation (all within three months) so marked as to lead to the suspicion of malignancy. The patient was seventy-two years of age, and had rapidly grown so weak as scarcely to be able to be out of bed. Within three months after the removal of the colloid polycyst (which was accomplished in eleven minutes from the first touch of the knife to the tying of the last suture in the abdominal incision) the patient had gained twenty pounds in weight, and is now, eight years later, still in perfect health.

I have seen the twisting of the pedicle of an apparently previously normal ovary produce an oedematous enlargement of the ovary to the size of a large hen's egg, with symptoms sufficiently severe to warrant me in opening the abdomen and removing the ovary. In this case there was no actual ovarian tumor before the torsion. Olshausen says that only one instance of this kind is on record by Rokitsansky, but in that case the ovary was adherent in an inguinal hernia.

The *differential diagnosis* is not always easy, the difficulty being chiefly to distinguish between an acute appendical abscess and an ovarian cyst with twisted pedicle on the right side.

Such a case occurred to me only a few weeks ago. A girl, thirteen years of age, was brought to Mount Sinai Hospital at 3 p. m. with the diagnosis of appendicitis, and was admitted to the general surgical service. On examining her, the house surgeon, Dr. W. M. Brickner, found a tense, prominent swelling of the size of a coconut in the middle of the subumbilical region, and shrewdly questioned the correctness of the diagnosis. He had her transferred to my service, where I saw her on the same day. The history was that the child had two previous similar attacks of acute abdominal pain during the past few months. I found a partly tense, boggy swelling in the anterior vaginal vault (the hymen and vagina readily admitted the finger); the uterus was retroverted and two inches and a quarter deep. A fluctuation wave extended from the summit of the abdominal tumor to the vagina. In spite of the age of the girl, I diagnosed an ovarian cyst, and from the acuteness of the attack, the temperature of 101.5° , and rapid pulse, suspected torsion of the pedicle. The boggy feeling of the vaginal portion of the tumor induced me to hazard the diagnosis of a dermoid cyst, but herein I was mistaken. But on diagnosis of ovarian cyst with twisted pedicle was confirmed at the operation on the following day, when a cyst of the right ovary with a pedicle twisted three times was removed, each twist doubtless representing one of the three attacks

of pain, etc., given in the history. There was a small amount of free serous fluid in the abdominal cavity. The cyst was almost black, no adhesions, and at its lower portion, just above the twist, the cyst wall was cedematous and contained a large, diffuse blood clot, which had given the boggy feel to the vaginal portion of the tumor. The left ovary contained two cystic Graafian follicles which I obliterated by a single puncture in each with a sharp Paquelin tip at red heat, then dropping the ovary. Convalescence was absolutely uneventful; on the fourth day the child was reading a novel. Neither pulse nor temperature rose above the normal.

It is this case which induced me to carry out a long-contemplated purpose to write up this subject.

Curious to say, on the very next day a woman was admitted to the general surgical service with the diagnosis of appendicitis, there being a diffuse, dull mass in the right ilio-chondriac region, with elevated pulse and temperature. On opening the abdomen over the swelling, Dr. Gerster found, instead of the expected appendicular abscess, an ovarian tumor with twisted pedicle, adherent to the abdominal wall.

Several years ago I saw in consultation with Dr. George A. Macdonald a woman with a large, diffuse, dull swelling in the left side of the abdomen, extending from the level of the umbilicus to the left twelfth rib. It appeared to be entirely distinct from the pelvis, the organs of which seemed normal. As she had a moderate rise of temperature, and the swelling was said to have come on gradually, I suspected an abscess in the abdominal wall, or at least connected with it by adhesions. On making an incision over the swelling and dissecting down to it, I found that it was intraperitoneal, and from the color of the sac probably ovarian. The sac was closely attached to the parietal peritoneum, but easily peeled loose after its serous contents had been evacuated. It proved to be not an abscess but an ovarian cyst with a twisted pedicle fully six inches long and as thin as thick white packing twine, and so brittle that it broke as the emptied cyst was delivered. The cyst was of the right ovary, although adherent to the left side of the abdominal wall, where it had been nourished by adhesions. There was no need of ligating the pedicle, as it was entirely bloodless. Recovery was uneventful.

It would scarcely be expected that an ovarian tumor could find space to permit of its being rotated and its pedicle twisted during the latter part of pregnancy; and still I have seen such a case. A year ago I was asked by Dr. A. G. Gerster to see with him a lady in the ninth month of her first pregnancy, who a few days previously had been seized with the symptoms of acute appendicitis—sharp pain, resistance and circumscribed dullness in the right iliac region, chills and fever. Dr. Gerster wished my opinion as to the best course to pursue with regard to the pregnancy, whether it might not be advisable to induce labor and deliver at once, either during or imme-

diately after the evidently urgent operation, in order to avoid the possibility of septic infection of the genital tract or the rupture of intestinal adhesions about the appendicular abscess if uterine contractions should come on soon after the operation. I fully agreed with Dr. Gerster in the diagnosis of appendicular abscess; no other diagnosis seemed possible under the circumstances, and also as to the necessity for immediate operation. But in the light of previous experience (see *Medical Record*, December 1, 1894, where I reported the first case on record of appendicular abscess during labor, and later observations, *Record*, March 23 and October 26, 1895), I recommended an expectant obstetric policy in the hope that Nature would unaided effect normal delivery, adding that in case of need the fresh appendicitis wound could be temporarily closed with sutures under the chloroform anesthesia of labor, so as to avoid any injury to fresh adhesions by the contracting uterus. The patient was transferred to a private room at Mount Sinai Hospital, and Dr. Gerster operated two hours later in the usual manner. To our surprise, instead of the expected abscess, when the peritoneum was incised a black tumor of the size of a large fist appeared which proved to be the right ovary with a tightly twisted pedicle. This was tied, the tumor removed, and the incision closed. Labor came on within twenty-four hours and terminated spontaneously. Recovery was uneventful.

There remains but one more word to say regarding the treatment of an ovarian tumor with a twisted pedicle—namely, that the tumor should be removed as soon as the diagnosis is made, or, if the latter is doubtful, an exploratory incision should settle the question.

It is not safe to expect or wait for the preservative assistance of Nature in furnishing fresh nutrition to the strangulated tumor by means of adhesions, and still less for the untwisting of the pedicle. An early operation promises a speedy recovery, and this may be one of the instances where a good rule is to operate first, and to make the diagnosis afterward.

20 WEST FORTY-FIFTH STREET, December 26, 1898.

ANTISTREPTOCOCCIC SERUM IN EPIDEMIC CEREBRO-SPINAL MENINGITIS.

By CHARLES P. McNABB, M.D.,

KNOXVILLE, TENN.,
PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE
IN TENNESSEE MEDICAL COLLEGE.

PERHAPS I should offer an apology to the readers of the *Journal* for reporting these two cases without waiting for a larger experience with the antistreptococcic serum in the treatment of epidemic cerebro-spinal meningitis, but, as that disease is prevailing in so many places at this time, I think I will report the facts as I saw them, and ask others to assist in finding the true

value, if any there is, of the serum treatment of this disease of such appalling fatality.

CASE I.—On the morning of the 21st day of January, 1899, I was called to see Mrs. S. B., aged twenty-four, in consultation with Dr. T. N. Ellis. Her personal history was negative preceding the present illness, which began at about 11 P. M. on January 19th. She was awakened from sleep by a chill, with intense pain in the head and neck, accompanied by nausea and vomiting. The muscles of the neck soon became sore and somewhat stiff, causing pain in moving the head. Dr. Ellis was called on the following morning and gave a calomel purge, also morphine to relieve pain. At the time of my visit the patient was moaning with pain, her head was slightly retracted, and her neck was stiff. She was semi-conscious. The conjunctiva were red, the eyelids were swollen, the pupils were rather sluggish, but responded equally to light, the face was flushed, there were a few herpetic vesicles around the mouth, the limbs were flexed, and the right knee was painful and swollen. The temperature was 100° F.; pulse, 60; respirations, 34. The bowels had been moved by the calomel, and urine was passed naturally and without difficulty.

The diagnosis was that of cerebro-spinal meningitis. A mustard plaster was applied to the spine and ten drops of a saturated solution of potassium iodide were ordered every six hours, with a quarter of a grain of morphine as often as might be necessary to control restlessness and relieve pain. A milk diet was ordered, and water was given at regular intervals. Under this treatment the conditions remained practically unchanged until the evening of the fifth day of her illness, when she rapidly grew worse in every way. Her pulse ran up to 160 and her temperature to 102.5° F.; the respirations became shallow and very irregular; and there were muttering delirium, complete unconsciousness, and involuntary discharges from the bowels and bladder, the *tout ensemble* indicating an early dissolution.

I had in the preceding few weeks seen other violent cases of the same nature, and was painfully aware of the futility of the ordinary methods of treatment, and, while meditating over these facts, had concluded that in the absence of a specific serum like that of diphtheria benefit might follow antistreptococcic-serum injections, inasmuch as the *Diplococcus intracellularis meningitidis* is found almost exclusively in the multinuclear leucocytes, as the exudate is composed largely of multinuclear leucocytes, as this leucocyte plays an important rôle in the formation of purulent collections, and as pus is a pathological factor of such prominence in cases of death from meningitis after a few days' illness. I concluded to try the serum in the next case that I regarded as hopeless, and had ordered and received from Parke, Davis, & Co. a supply of their product. I did not use the serum earlier in this case because, so far as I know, I was the first to try it in meningitis, and I did not have the courage to experiment on a human being so long as I could see a ray of hope for recovery.

On January 24th, at 7 P. M., which was the fifth day of her illness, I injected ten cubic centimetres of antistreptococcic serum into the subcutaneous areolar tissue

of the abdomen, and advised Dr. Ellis to repeat the dose at his morning visit if the patient lived until that hour. A thirtieth of a grain of strychnine was to be given every three or four hours, and an ounce of whisky every two hours if she could swallow it.

On the 25th, at 8 A. M., Dr. Ellis gave another injection of ten cubic centimetres of the serum and ordered the strychnine and whisky continued as before. I saw her at 4 P. M., and was astonished to find her perfectly rational and calling for food. Her respirations were 20, her temperature was 98.5° F., and her pulse was 106. The pain in the head was very much easier, the neck was still sore and stiff, but the head could be moved from side to side without pain. Another injection of ten cubic centimetres of serum was given and the strychnine and whisky were continued. From that time to this she has had a slow but satisfactory convalescence, except for occasional headaches, which annoy her, and a decided constipation, to which I attribute a part of her headache. There was no eruption at any time except herpes labialis.

CASE II.—P. P., a teamster, aged twenty-two, had a chill late on Sunday evening, February 5th, followed by severe headache, vomiting, great restlessness, and wild delirium. So great was his excitement that it required two men to hold him in bed for several hours, on Monday the 6th, notwithstanding his physician, Dr. Barr, had given morphine freely. I saw him in consultation at 8 P. M. on the 6th, after he had been ill about twenty-four hours. He was lying on his left side in deep coma, with the limbs flexed and in tonic spasm, the head retracted, the neck as stiff as a rod, the face flushed, the conjunctiva congested, the pupils contracted, the eyelids swollen, and the jaws closed like a vise. The temperature in the axilla was 97° F.; pulse, 80 and weak; respiration, 36; the trunk was thickly studded with petechia and purpuric spots.

The diagnosis was that of cerebro-spinal meningitis of the fulminant type.

An injection of ten cubic centimetres of antistreptococcic serum was given, and hypodermic injections of a thirtieth of a grain of strychnine were administered every four hours.

On the 7th, at 8 A. M., the patient was rational and expressed himself as very comfortable. The headache had ceased, and he could move the head without pain, but could not bring the chin forward. He said: "The leaders are too short." The muscles of the extremities felt sore and weak. The bowels had acted from ten grains of calomel given twenty-four hours before; the bladder acted freely; pulse, 104; temperature, 99° F.; respirations, 26; facial appearance unchanged except that the pupils were dilated, but responded slowly to light. Another injection of ten cubic centimetres of serum was given. Milk diet was ordered, and he was to take water when he desired it.

Two persons with the fulminant form of the disease had died in his vicinity three or four weeks before, one in twenty-five and the other in about thirty hours. One of them was under my care, and the symptoms were precisely like his. Like him, they were strong, healthy men in the full vigor of robust manhood, and the change in this patient's condition was a marked and so in contrast with theirs that I invited my friend and colleague, Dr. Campbell, of the First Tennessee Hospital for the Insane, to visit him with me, which he did at noon. At this time he was wonderfully improved in appearance and wanting to sit up in a chair. He raised

himself up and turned over in bed with perfect ease to show Dr. Campbell the purpuric spots on his back, and expressed himself as feeling quite comfortable.

At 6 P. M. he said he did not feel so well and complained of weakness and dizziness. His nose was bleeding a little and I noticed that the blood was very pale and did not coagulate readily; respirations, 30; temperature, 98° F.; pulse, 110. A thirtieth of a grain of strychnine was given every four hours and an ounce of whisky every two hours was ordered. Another injection of ten cubic centimetres of serum was given.

On the 8th, at 8 P. M., he was very restless and semi-conscious, the face was pale, the eyelids were swollen, the conjunctivæ were red, and the pupils were dilated and unequal. The right one responded slowly to light, but the left one did not. His head could be moved by the attendants, but it caused him to wince. The right arm was completely paralyzed, and the right leg partially so. The bladder was full of urine, and twenty ounces were withdrawn by a catheter. Respirations, 20; temperature, 97.8° F.; pulse, 80, slow, hesitating, full, but very soft and compressible. He swallowed with difficulty. He became quiet after the use of the catheter and remained so for several hours until the bladder re-filled. Strychnine was continued, and the juice of a lemon and four ounces of whisky were ordered, in teaspoonful doses, every half hour if they could be swallowed. The serum was discontinued, as it was not thought possible for it to relieve the cerebral hæmorrhage which I believed had occurred.

At 6 P. M. the coma had deepened and the right leg was completely paralyzed; the pupils were dilated and fixed; the dilatation of the left was still greater than that of the right; there was opisthotonus, and the head inclined to the left side; the temperature was subnormal; pulse, 130 and thready; respiration irregular and noisy. Fifteen ounces of urine were withdrawn by the catheter. The strychnine and whisky were continued.

On the 9th, at 8 A. M., the patient was in deep coma, with rapid and noisy respirations; pulse, about 160 and very feeble; temperature not recorded. Opisthotonus increased and the head was drawn to the left. The pupils were widely dilated and paralysis of the lower extremities was complete. Sensation and some motor power remained in the left arm. The bladder was full of urine. Thirteen ounces were withdrawn by the catheter. Death occurred a 12.45 P. M. An autopsy was not allowed.

From the foregoing reports I am inclined to the following conclusions:

I. The antistreptococcic serum has a decided stimulant effect on the nerve centres in meningitic coma, but the same results might follow a warm, saline hypodermoclyster.

II. It probably increases phagocytosis and in this way has some antidotal effect on the *Diplococcus intracellularis*.

III. It probably prevents purulent infection of the exudate, and thus lessens the danger in all cases in which the patients survive the first three or four days.

IV. From my observation of these cases I am quite hopeful that an antidiplococcus-intracellularis-meningitidis serum can be produced which will have a decided effect in controlling the terrible toxæmia of meningitis,

and that the associated effect of antistreptococcic serum after the second day will assist in preventing streptococcic infection of the exudate.

V. I am well aware of the fact that the improvement which I saw in these cases may have been a coincidence and not due to the use of the serum, but if it was it was entirely unlike anything I have ever seen before in such cases.

VI. I am satisfied that in Case I the patient would have improved faster if the serum injections had been continued daily for several days longer, and, if I should meet with another case like Case II, I would give from forty to sixty cubic centimetres of the serum in the first thirty-six hours.

THE TREATMENT OF NORMAL LABOR.*

By S. MARX, M. D.,

SURGEON TO THE NEW YORK MATERNITY.

THE line of demarcation between normal and abnormal, or, more properly speaking, physiological and pathological labor, is one so sharply defined that it is absolutely impossible, in many cases, to state where the former ends and the latter begins. It is customary to call labor a physiological process. To this I agree in the broadest sense of the term, for the sole reason that the efforts of Nature in an otherwise healthy woman is, or should be, always a physiological process. But further than this I can not go. Obstetrics as taught in the lecture rooms and from books is always beautifully graphic, terse, and to the point; but how different is the case at the bedside of the parturient woman! Who can ever possibly certify that this so-called physiological act may not at any moment carry the woman and her child into the gravest and most desperate states? Why do all women dread childbirth, even as did patients about to be operated on in the preanæsthetic days? Does Nature produce such agonizing tortures in fulfilling her other physiological functions? Is not pain in itself incompatible with such normal functions? To make labors absolutely painless is beyond us at present. Such periods could be called "Utopian periods"; but this ideal, the Utopian period, has not as yet arrived. Surely, and I have the greatest hopes that the next century will see this, not through making "labors" an elective measure, such as we are in a position to do to-day by general anæsthesia, but by direct action in the vital uterine nerve centres, to be reached by a cataphoretic current, diffusing to those centres and benumbing them by some analgetic measure or other. Therefore, to call labor a physiological process is wrong, and the longer I practise midwifery the stronger grows the belief, nay, the conviction, that we are dealing with a pseudo-physiological condition strongly tending to and always verging on a pathological state.

* A paper opening a discussion before the Metropolitan Medical Society, December 27, 1898.

and we never can know when the one merges into the other. We must presuppose that the woman has been carefully watched during pregnancy; her kidneys, liver, skin, etc., have all been attended to, the pelvis carefully and thoroughly measured, and its size estimated, the adaptability of the foetal head to the maternal pelvis accurately judged. All this attended to, so that the woman, *not* the patient, goes into labor in the best possible condition of health. Thus we are prepared to attend a woman physically and physiologically well in a time every moment of which, like Sherman's description of war, is hell. What are the duties of the accoucheur? Is he the perfunctory individual of whom the average layman, and I am ashamed to say, even the physician, speaks of tersely. Any one can deliver a woman. What is there in obstetrics? Ah, gentlemen, "here's the rub!" No physician is better than a bad one. The highest duty of the accoucheur is not to deal alone with prophylaxis as to present states, including sepsis, lacerations, etc., but to place the woman in so perfect a condition, and to make that condition so permanent a one that her health is as good after as before the accouchement. And what is the secret of this success? It is explained in one word—"asepsis." I fully realize the difficulty to be encountered in approaching this subject, in the light of the much-mooted discussion as to the bacteriological findings of the parturient vagina. Naturally, bearing strongly upon the subject now advanced, is the status of the vagina on the one hand, and the condition as to surgical cleanliness on the part of the attendants, paraphernalia, etc., on the other hand. From a vast amount of scientific research we must presuppose the larger number of "parturientes" to have a vaginal secretion, which possesses to a decided degree an inhibitory action which bears directly on pathogenic organisms—i. e., streptococci, staphylococci, etc. A secretion which possesses such qualifications obtains in the normal vagina at all times. This secretion is acid to a marked degree, sticky, and gelatinous. Its inhibitory action depends upon the presence of lactic acid produced by *Dodlein's bacillus*. When we find such vaginal secretion present, which can be proved clinically by sight and touch, we have the vagina prepared sufficiently, without artificial preparation, to conduct labor scientifically; and under these conditions no ante-partum douches, scrubbing, etc., are allowable, for if such means are employed the possibility of producing an infection, or the destroying of Nature's protective means are ever present. So firm is my confidence in the ability to destroy, on the part of Nature, every possible pathogenic germ that may be introduced by operative interference, that when the asepsis of the operator can not be questioned, there never is allowed a uterine or vaginal douche, either before, during, or after the interference. Different is the condition when, from bacteriological evidence, this inhibition does not obtain. Under the conditions we have a vaginal secretion which is alkaline in

reaction, profuse in amount, malodorous, and purulent. Here we have to deal with what in most cases is a gonorrhoeal infection. Thus the indication is to treat before and to anticipate the labor by prophylactic douches, profusely and repeatedly given; and if, when labor sets in, and the discharge is not the normal one, surgical scrubbing, even as is done before a major vaginal operation, is distinctly called for. The use of green soap, alcohol, and bichloride is the *rigime*. Approaching the accouchement of a healthy woman, what subjective preparations from a modern standpoint are to be taken? No vaginal douches are allowed before, during, or after labor. The external genitalia are thoroughly scrubbed with soap and water, and this very briskly to insure mechanical cleanliness; this is followed by washings with dilute alcohol, and again rinsed with a bichloride solution, 1 to 2,000. The strictest attention must be paid to the hands of the examiner: for since we have so strongly asserted that a healthy parturient is antiseptic or aseptic, there can be only one source of infection directly or indirectly, and that the accoucheur and from without. Self-infection is so rare that it hardly has a bearing on the subject. The average hand-cleaning performance of the practical physician is more in the line of an "opera-bouffe" than anything else, a veritable parody, and an insult to the memory of Semmelweis and Lister. There should be thorough surgical scrubbing, mechanical and chemical, by what means I care not, but let it be thorough. The method I employ in hospital and private practice is to use, step by step, green soap, ninety-five per cent. alcohol, and 1-to-1,000 bichloride solution, and the scrubbing is rigidly and carefully done by a sterile brush. Where I have recently come in contact with a septic case, a thorough permanganate-of-potassium-and-ovalic-acid scrubbing is gone through with at home. Now, as to the manner of examining the patient. This is a step which I know may carry me on dangerous grounds. The school of obstetrics is to-day divided into two classes: those that believe in conducting a case entirely by external methods—the so-called abdominal palpationists—and again those who would have us employ both external and internal examinations. With the latter I throw my entire weight of experience. The German school originated the external method, alleging for it a reduction in both the mortality and the morbidity rate. This, from observation of their own records and our own hospital records, I absolutely deny.

Further, they state that in ninety-five per cent. (the exact percentage I can not remember) of their examinations the diagnosis of position and presentation was correctly made by simply "laying on of hands." This is certainly grand and true as far as it goes, but when one recollects that in ninety-five per cent. of all cases both presentations and positions are correct and normal ones, I can not for the life of me understand why such glorification attaches itself to a method which, to my mind, means lack of confidence and trust on the part of the ac-

coucheur. It means simply that these men do not trust their own hands. A practitioner who does not know how to render his hands clean has no moral right to practise midwifery; and, on the other hand, a physician who *can* trust his own asepsis, can introduce his hands, not once but a thousand times into the vagina, even as the abdominal surgeon can trust his as well as those of his assistants in his particular field of operating; for, is the vagina more susceptible to pathogenic germs and to infection than the peritoneum? It is my invariable rule to examine as often as is necessary and consistent with the welfare of the mother and child. When the condition demands it, as, for instance, in guiding an occipito-posterior position to an anterior one, I do not hesitate to keep my fingers, if necessary the hand, in the vagina for half an hour or longer. It is also an invariable rule to make a diagnosis of the presenting part, and if the case is at all dark, there is absolutely no hesitancy in introducing the clean hand into the uterus for purposes of exploration. It must ever be remembered that the presence of a head as the part in contact with the examining finger does not mean that everything is all right, but I fear that the ordinary practitioner in his formal examination always rests satisfied so long as the hard, round head is felt as the advancing part. There is such a thing as a malposition of a normal presentation, as witness an occipito-posterior case, and here I am not backward in stating that more trouble and chagrin, more fever, more deaths occur as a result of this complication than any other in the entire domain of obstetric surgery.

As to the position of the patient during active labor, especially during the second stage, it behooves me to state that after careful consideration of the subject in a great many labors, I have found that the labors were much shortened and more rapid when the patient was placed on that side corresponding to the position of the presenting part, and the rationale of such postural treatment was thought to be the overcoming of the ever-present uterine obliquity, thus favoring, and to a marked degree influencing, either the flexion or extension depending on the presence of a face or vertex presentation. Even when the head begins to distend the perineum the side position is favored. In our ordinary soft beds the buttocks sink so deeply in the dorsal posture of the patient, that more often than not the perineum is with difficulty seen, and thus its management is materially interfered with, while with the woman on the side the entire perineum can be seen and manipulated with ease. Further, in the side position the occiput of its own weight is thrown forward and liberates itself thus more naturally and more readily than when the patient is placed on the back. It is at this stage—that is, when the head reaches the pelvic floor—that drop doses of chloroform are gradually given and increased, but only during the pain, so that when the head has cleared the perineum the patient is fully narcotized to the obstetric degree.

The most important question now comes up for discussion—namely, the perineum, and its care. The old term, supporting the perineum, is a misnomer and a misleading term, since the greatest success in the preservation of the perineum is attended by not touching the perineum at all, literally speaking, but by managing the head in such a fashion as to produce continuous flexion of the head to the point of superflexion, if necessary forcibly liberating the occiput and clearing it from beneath the symphysis, and in this fashion engaging the nape of the neck, or, properly speaking, the suboccipital point, underneath the symphysis, before the attempt is made to extend the head. We thus liberate a small diameter of three inches and three quarters, the suboccipito-bregmatic, for one in an improper mechanism of five inches, the occipito-frontal. Thus it is that the mechanism of perineal preservation is due not to supporting that part, but to its management. We may be asked whether, sticking close to this method, we have ever torn a perineum? and the answer to this is, Yes, hundreds! There is no man living who has not had his share of perineal tears, and among my own, I must say, there have been many small and large ones. Proud I am to admit it, for the reason that I have delivered a great many hundreds of women, and I always look for lacerations both externally and internally. Those who never have had any lacerations can be thrown into three classes: 1. Those who have never had a labor case. 2. Those who never look for them. 3. Those who hate the truth. Where there is danger of a laceration, a large experience has taught that bilateral episiotomy will not prevent its occurrence, and, on the contrary, the advancing head will tear these two superficial incisions further and produce a large irregular tear on either side. In one case, on one side the ischial tuberosity was exposed. My method is to fully dilate by cutting the vulvar orifice completely by a deep vulvo-vaginal incision, nothing more or less than a deep unilateral episiotomy. Thus we get a clean surgical wound readily sewed up, in place of two irregular ragged tears, as produced by the superficial incisions. When the perineum already begins to tear, or acts like wet blotting paper, the quicker the head is extricated the smaller the tear; since these lesions are produced by pressure against the perineum; an artificial anemia becomes evident, with a consequent rapid sloughing of the parts.

Finally, we come to the treatment of the third stage of labor. As soon as the fetus is born, the cord is tied in a fashion original, I think, with me. Three ligatures are used, two at the usual site. The cord is now carefully pulled upon until it is taut, and at the point of exit at the vulva another ligature is placed. Its object is thus explained: The placenta can not move without pushing the cord before it, so that the position of the third ligature tells me exactly where the placenta is. If the ligature is still at the vulva, the placenta has not moved; if three or four inches from the vulva, the pla-

centa must be in the vagina. This may at first appear an unimportant prophylactic measure, but I have been so often called to remove an adherent placenta only to find that mass in the vagina or cervix, that a measure of this kind will at least prove that an adherent placenta is one of the rarest of all obstetric complications. Since placental separation begins with commencing active uterine action, it is my custom to attempt to express with the first good pain following the birth of the child. Where a perineum is torn, an almost invariable custom is to sew up at once, tie temporarily, remove the placenta, and then permanently place the sutures. These parts are thus so obtunded from the pressure and the superficial narcosis, which has not time to wear off, that the needle pricks are hardly felt. Where the afterbirth does not readily follow, successive Credé manipulations are performed with each uterine contraction. Where this does not suffice, a modification of Kristeller's procedure is always successful, except in those cases, fortunately very rare, where there is total adherence. In the Kristeller method of expression both hands are used together, each separately doing the simple Credé manipulation, the thumbs being in contact, the operator facing the patient.

This outlines in general the treatment of normal labor, and I am cognizant of the fact that much should be added to make this article complete. To fully detail all the nice points and useful devices which it would be my pleasure to add, would necessarily lengthen this article to the dignity of a text-book. But this is simply impossible, and my only hope is that this can be successfully added to by the many gentlemen present, who are or at one time or other have been interested in the much-neglected art and science of midwifery.

947 MADISON AVENUE.

SPASM OF THE TENSORS OF THE VOCAL CORDS.*

By JOHN EDWIN RHODES, M. D.

MACKENZIE (1), in 1880, was probably the first to accurately describe this condition, although Schmitzer (2), in 1875, Schech (3), in 1879, and Prosser James (4), in 1879, reported cases which manifested some what similar symptoms of a spasmodic character. I find on consulting the literature of the subject that these spasmodic affections of the larynx have been treated of by different writers, as "stammering of the vocal cords," "spastic aphonia," "spastic dysphonia," etc. I believe they may be classed together, and, although the cases which I shall report may properly be classed under the title given by Mackenzie, it would, perhaps, be preferable to place all similar cases of spasmodic affections of the larynx under the uniform title of "dysphonia

spastica" (5). It is certainly a rare affection. Mackenzie saw but thirteen cases. I have found a few on record besides those mentioned above. Among these, Michael (6), Heyman (7), Oltuszewski (8), Massuci (9), Landgraf (10), Onodi (11), Rethi (12), Knight (13) have reported cases most of which differ materially from those I shall report in their manifestations. In many the affection seems due to an abnormal use of the voice or to its overuse, but it may be manifested only after many years of such use, and it is possible that some neuropathic condition which is not well understood is the cause of its development. Landgraf believes that degenerative processes of the nervous system (*e. g.*, multiple cerebral sclerosis) are important etiological factors. Fraenkel (14), Michael, Schech, and others suggest that it is an occupation neurosis similar to writers' cramp. Krause (15), in reporting a case of aphonia with dyspnea (laryngeal) spastica, arrived at the conclusion, from the history and status of the case, that it was one of incipient multiple sclerosis. Catching cold has been named by Mackenzie as an apparent cause of the complaint in some cases coming on suddenly. Oltuszewski has reported cases connected with nasal affections which were relieved by treatment of the latter. Browne (16) believes it a common affection, considers it neither of neuropathic nor myopathic origin, but a result of improper voice production dependent upon wrong breathing while speaking. No post-mortem examinations have been reported, and it is probable that the pathological changes would be of too obscure a character to admit of satisfactory study.

The symptoms in these cases appear on every attempt at phonation. The whisper voice is usually perfect. The speaking voice is feeble, husky, wavering, and jerky, with perhaps change from low to high tones frequently in the attempt to speak more clearly. In the beginning there may be simply a difficulty in getting started, and after speech has been in progress for a time the tones may be clear and unwavering, or there may be the involuntary break in phonation only after speaking for a time, the voice changing to the high-pitched, jerky voice, as in Knight's case, reported to you in 1896. In Schmitzer's case there was complete aphonia and dyspnea in speaking only, accompanied with some facial spasm. In Schech's case there was some pain and oppression felt in the throat in speaking, and finally complete aphonia, and in another case the voice, at first normal, changed to falsetto, followed later by aphonia, accompanied with spasm of the vocal muscles. In the Prosser James case there was an intermittent loss of function of the cords during severe colds, and whole sentences were dropped immediately. In Michael's case there was loud stridor on inspiration, and a hoarse voice, and also dyspnea. Finally, in the last case which was relieved of dyspnea, and the voice becoming normal. This fact seemed to prove the existence of paralysis, not of paralysis. One of Michael's cases was a female

* Read before the American Laryngological Association at its thirtieth annual congress, May 16 to 18, 1898.

singer troubled with hoarseness. Here the abduction of the cords was found normal, but in adduction, on the slightest effort at vocalization, the glottis was completely closed and no rima glottidis could be seen. Landgraf has given the record of a woman in the later stages of pulmonary tuberculosis. There was apparently a participation of the diaphragm in the glottic spasm. Onodi recites a case in a hysterical girl with loss of voice and difficult breathing, relieved by ether and cured by hypnotic suggestion. Rethi reported an instance last year of a female singer whose voice "stuck" as she tried to pass from one register to another, and a laryngoscopic examination showed at the moment of change an elongation and tension of the cords with scarcely a perceptible separation and no tone produced. In this patient he thought there was a reflex starting from the nose, and the higher register muscles were affected.

Dr. E. Fletcher Ingals and myself have observed five cases, the reports of which are as follows: Three of these I have recently had an opportunity of studying carefully.

CASE I.—S. O. J., clergyman, native of Scotland, aged fifty-six years, gives the following history: His father, who was a miner, died at eighty-one of old age; his mother at about thirty-five of consumption. He has no full brothers or sisters. His father was deaf and dumb, as were his father's brother and sister. Two of his mother's brothers were stammerers. These are interesting facts. He has two half brothers who are healthy and have no abnormality of speech. He was rather a frail child, and during his early life endured many hardships, doing severe labor in the mines and having insufficient food. He has been usually healthy, with the exception of an attack of yellow fever eight years ago, and at that time suffered from nervous dyspepsia. Since then he has also had yearly attacks of hay fever, beginning in the middle of August and continuing until cool weather. His temperament is markedly neurotic, but the strain of an exacting position always increases his nervous symptoms. Since the inception of hay fever, until recently, he has used freely as a spray several times a day, and sometimes much more frequently during the summer, a solution containing ten grains of cocaine and ten grains of boric acid in eight ounces of water. He has always had some dread of public speaking and feared that at some time his voice might suddenly fail him. Realizing that his voice had not carrying power he raised its pitch, and spoke with greater force. There was, however, little difficulty in speaking until a year and a half ago. This came on gradually. In the beginning there was huskiness of the voice and slight difficulty in public speaking, very little in ordinary conversation, but often the voice became clear after a few moments' use. No dyspnoea has ever been present. Soon he found that by changing the pitch to high tones he spoke with less effort and the voice was clear. Since August, 1897, there has been more interference with speaking in the chest tones. Speaking does not tire the throat greatly. Early in the history of the case, in beginning a sentence he often found that with the first effort to speak aloud no sound was produced, and it was necessary to attack the sentence again. After his diagnosis was under way,

and his attention was entirely occupied with the subject in hand, he spoke easily. Later his voice became unsteady in the chest tones in all attempts at phonation. Now, in conversation, the voice is slightly husky and repressed, is tremulous, jerky, and strained in character and irregular in pitch, the sentences being often preceded by a very full inspiration, as he had found that a full chest cavity enables him to speak with greater ease, though it does not improve the voice. In the midst of a sentence he often "yawns." The whisper voice is normal. At present his general health is excellent. An examination shows a little thickening of the nasal mucous membrane, with marked deviation of the septum to the right. Before coming to us his uvula had been amputated without benefit. The fauces appear normal; the larynx is normal except a moderate and diffuse congestion of the cords; there is also a mild congestion of the tracheal mucous membrane. The action of the cords is nearly normal. On phonation the alignment is at first perfect, but on continuing the effort there is a marked relaxation of the internal fibres of the thyreo-arytanoids, but in the higher tones the tension is perfectly held. The muscular action in abduction and adduction seems perfect. The faucial reflex is lost, the scapular is absent, the ankle clonus is absent, but the plantar reflexes and the patellar tendon reflex are exaggerated. All the others are normal. No abnormal signs are obtained over the chest. He has now rested from his professional duties for over six months, he has had electrical treatment for three months, and has had local and constitutional treatment of various kinds without benefit.

CASE II.—L. C., clergyman, aged sixty-nine years, first came under observation in July, 1886, complaining of a strained feeling in the larynx at times during the previous six months, more marked when tired and worried, and more perceptible during ordinary conversation. Ten years previously he had had a spasmodic affection of the larynx, from which he fully recovered. At the time he came under my observation his larynx showed a paresis of the right cord, the movements being slow both in abduction and adduction. A few applications of mild astringents were made, and he left in a few days for his summer vacation. In September he returned and resumed service in his pulpit, feeling little better, but preaching with comparative ease. He was placed on phosphate of zinc, a quarter of a grain; strychnine sulphate, a twenty-fourth of a grain; and arsenious acid, a twenty-fourth of a grain, with local applications of zinc sulphate, two grains to the ounce, and later copper sulphate, ten grains to the ounce. An examination of the larynx at this time showed free movement of the cords, but there was congestion of the edge of the right cord, and it slightly overrode the left in phonation. In November an examination showed sluggishness in the movement of the right cord. Occasionally he could preach as well as ever. He continued his services regularly from this time, and we had no opportunity of examining him again until September, 1890, when he again began to have his nervous trouble. He could preach once or twice weekly fairly well, but each afternoon and toward evening he experienced difficulty in ordinary conversation. He complained most of the effort in public speaking, the necessity of forcing the voice, and the tired condition of the muscles of the larynx, throat, and chest during and after speaking. He was taking at this time strychnine sulphate in one-twenty-fourth grain doses, which he continued for some weeks. In October he complained of some difficulty

in respiration, although there was no marked dyspnoea. The throat felt tired and uncomfortable at night. Except early in the day, when his voice was good, he was obliged to "jerk out" his words. He could read the service and preach in his usual good voice, but in conversation there was spasmodic action of the cords and an involuntary change to the falsetto tone. He continued his services quite regularly from this time until 1893, when he retired permanently from his work, in the meantime consulting many leading throat and nerve specialists in America and Europe, and being treated with electricity, hypodermics of strychnine, etc., with no benefit. We saw him again quite recently and found his condition much changed for the worse. His general health is robust, his intellect as keen and vigorous as formerly, his appetite excellent, and he sleeps well. On any attempt to speak or whisper there are violent spasms of the muscles of the larynx, the face, and some of the muscles of respiration, and the voice is uncertain, broken, and uncontrollable, changing rapidly from one pitch to another. He continues conversation only with great effort, but can say half a dozen words with perfect enunciation in a loud oratorical voice, such as he was wont to use in his pulpit. An examination of the larynx shows only slight congestion of the vocal cords, and the muscular action seems perfect. The phonation during laryngoscopic examination is excellent. There are no abnormal chest signs, or abnormal conditions of the nose or throat. An interesting fact in the case is that he has found that the use of cocaine in the nose will enable him to speak as well as he ever did in his life for one or two hours, and he has recently read a paper before a literary society of an hour's length, with perfect ease after its use. Experimentally, a minute quantity of a powder containing four per cent. of cocaine was insufflated in the nares. After a few seconds he remarked: "There, you see I can speak with perfect ease," and he could. It would be interesting to make applications of cocaine to other mucous surfaces—the larynx, the pharynx, and the tongue. We might thus determine whether we had or had not a reflex starting from the nasal membrane, but possibly the results here are due to the systemic influence of the drug. He volunteered the suggestion that if he could be placed under hypnotic influence he believed he could be helped, but efforts in this direction have been unsuccessful. Just now he is taking a systematic course of breathing exercises.

CASE III.—Sister C., aged twenty-five years, was first seen March 28, 1898. She has been a teacher in a convent nine years, and has also led the singing in the choir. She has been subject to colds during the last few years, and has frequently become hoarse, often losing the voice two and three days at a time, but up to September last the voice was usually clear and normal. At about that time she noticed that, while the voice was clear a part of the day, at about four o'clock in the afternoon she began to be troubled with dysphonia, and was obliged to speak in a whisper during the remainder of the day. Since January the dysphonia has been constant, and the voice has been affected during the entire day. In using the chest tones particularly, there is considerable muscular effort, and the voice will change from the chest tones to those of the upper register involuntarily and very abruptly; at other times the loud voice is lost entirely, quite suddenly, but she can speak easily in a whisper. She noticed a curious condition in singing. She says that "she seemed to have a double

voice, as if she had an accompaniment similar to that produced by striking the A and E strings of the violin together." After using the chest voice for a time, besides the pain in the larynx, there seems to be some swelling of the muscles externally, as she is obliged to loosen a silk handkerchief she is accustomed to wear about the neck. She says that the nose has been treated for hypertrophy by cauterization, and some treatment has been applied to the throat. There is no heredity in the family. She is of an exceedingly nervous disposition. About three weeks ago she had a slight attack of acute pleurisy, from which she has not fully recovered. She now has a slight hacking cough and a poor appetite; has lost about twenty pounds in weight, and complains of general weakness and a great deal of headache. There is a history of no other illness. An examination of the throat and nose showed that the nasal cavities were free and the tonsils moderately enlarged. There was some enlargement of the glands at the base of the tongue. Examination of the larynx showed the vocal cords clear and the upper portion of the larynx slightly congested. On phonation, at first the cords come together perfectly, but the ligamentous glottis fails to approximate perfectly, there being a space of about one millimetre. She has been seen but once, and was asked to avoid speaking in a loud voice, and was given arsenious acid, one thirty-sixth of a grain; strychnine sulphate, one twenty-fourth of a grain; quinine valerianate, two grains; camphor monobromide, three grains, four times a day.

In two other similar cases the records are not complete and the patients can not be found.

CASE IV.—P. L. J., male, aged fifty-one years, farmer. He was seen but once. For four or five years had trouble with his voice. It was feeble, high in pitch, strained and spasmodic, and seemed as if it required marked muscular action in the larynx to produce it. He could call cattle loudly by sucking in his breath. There were no abnormal appearances in the larynx.

CASE V.—T. S. F., male, aged thirty-three years, merchant. Had for two or three years previously a strained, catchy, and muffled voice, hoarse, jerky, and wavy in character, which was worse in damp weather, and talking was sometimes quite difficult. At times the voice was perfectly normal. The spasmodic action of the thyro-arytenoid and the abductors was evident on examination.

In two of these cases the improper use of the voice is plainly an element in the causation. In the first case there had been an effort for a number of years to accommodate the voice, which had little carrying power, to a large auditorium, and in order to reach the auditors in the rear the pitch was raised. In the second case the fault appeared to lie in the improper production of the voice, in cultivating the "accented ecclesiastics" to add to the effectiveness of the Episcopal service, but it seems to me evident that there was some other aetiological factor. In one case the affection did not appear until twenty-five years after the beginning of the patient's professional work, when it came on simultaneously with an attack of nervous dyspepsia and hay fever. The latter has persisted ever since. This patient has been under a constant nervous strain for several years, and the dysphonia has persisted in spite of treatment. There is a disturbance of reflex action. In the other, in which there seemed an element of hysteria, there has

been a long-continued and most vigorous use of electricity, tonics, absolute and prolonged rest, suggestion, etc., notwithstanding which the disease has steadily progressed.

In these cases we are forced to the conclusion that the disease is of neuropathic origin, probably located in the motor areas of the medulla. In the first patient a careful objective study has seemed to me to localize the spasm in the internal tensors of the vocal cords, as Elsberg (17) terms the thyreo-arytenoid muscles, the inner fibres of which, as stated by McCoy (18), "are chiefly concerned in fixing the free edge of the vocal bands in a state of rigidity." The picture shown by the laryngoscope in this case varied in the production of the chest voice and the falsetto. In the chest voice the vibratory action of the ligamentous glottis was evident, regardless of any action of the expiratory muscles, or a full amount of air in the chest, thus excluding one factor upon which Browne (19) lays stress. The alignment of the cords upon the attack in phonation is perfect, the arytenoids adducting perfectly. As the tone progresses the inner portions of the cords of the ligamentous glottis become lax and there is an elliptical opening with the production of the characteristic broken voice. In the falsetto voice, the action of the cords is perfect, and the tone is clear and unwavering. In the second case, however, there is, on every attempt at phonation, spasm in both lower and higher tones, and at the present time spasm of the muscles of the face and neck and some of the respiratory muscles.

The spasmodic action of the laryngeal muscles on attempt at phonation, with the production of the characteristic voice, but more or less perfect condition of the parts on laryngoscopic examination, are the essential points in making a diagnosis. The prognosis is unfavorable. Few cases are cured or much relieved. Two of the cases here reported have run the gamut of treatment by rest, lessons in proper breathing and use of voice, electricity, local applications, strychnine, arsenic, etc., in large and long-continued doses, and nerve sedatives, but are to-day in no better condition than when first seen. Dr. C. E. Mudge, an expert in treating stammering, after careful examination of the first case, concluded he could do nothing for him.

Prolonged rest for the voice and a general tonic course of treatment for the nervous system are indicated. Such nervine and general tonics as strychnine, arsenic, valerian, potassium bromide, quinine, iron, etc., are suggested. Electrical treatment has seemed to give relief in some cases. Astringent and sedative local applications have been used with some benefit, and the results in Oltuzewski's cases would indicate that any abnormal conditions in the nose and upper air tract should be relieved. It is an interesting fact that the use of cocaine in the nose in Case H seemed to relieve the spasm for a time, but the continued use of such an application could not be recommended. Ingals (20) recom-

mends prolonged rest for the voice, and then exercise in systematic reading in a low and unvarying monotone, discontinuing the exercise as soon as the voice breaks, and gradually prolonging the effort, if possible, and finally varying the pitch and intensity. We can not hope for a cure in any fixed line of treatment.

ANOTHER CASE OF BRONCHITIS AND PNEUMONIA FOLLOWING THE INHALATION OF A FOREIGN BODY.

By C. E. COON, M. D.,

DEMONSTRATOR IN ANATOMY, COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY.

On July 25, 1898, I was called to see Miss M. L., servant, unmarried, aged fifty-eight years; came to this country from Ireland when she was twelve years of age. She was of medium height, well nourished, and weighed about one hundred and sixty pounds. The family history was negative, and she had always been well; she could not remember having been previously under a doctor's care.

Two days before I saw her she had an attack of vertigo, accompanied by nausea and general malaise; later on the same day she had severe headache; there was no vomiting or chilly feeling. The following day an irritating cough developed and there was much soreness of the muscles, especially on the right side and back. At the time of my visit the cough and soreness of the muscles continued. The patient also complained of diarrhea; the tongue was coated and somewhat furred; the temperature was 102.4° F., the pulse 108. Percussion and auscultation over the lungs revealed nothing.

On the morning of July 26th I found the condition

much the same—temperature 102° F., pulse 104—and advised her to go to a hospital; in the evening of the same day she was admitted to St. Joseph's Hospital. The hospital records give the history as above; temperature on entrance, 102.8° F.; pulse, 114. The following day, temperature, 103.6° F.; pulse, 86; and an area dull on percussion was noted in the right lung posteriorly, but no râles could be heard. At this time the diagnosis of right central pneumonia was made by the hospital physicians, and treatment in accordance was instituted. For several days her temperature was high and pulse variable. On the evening of July 30th, during a paroxysm of coughing, she expelled a quantity of muco-pus, in which was found what upon examination proved to be a *huckleberry*. It was then learned that eleven days previous she had eaten huckleberries, but had no recollection of inhaling one, and had experienced no discomfort at the time. Immediately after the expulsion of the berry the temperature came down to normal and remained there. The cough continued with somewhat lessened severity, and she raised a little; but at no time, except when the berry was expelled, had there been anything like profuse expectoration. The patient convalesced quite rapidly, and on August 16th was discharged from the hospital. On September 17th I saw her again; the cough had not ceased entirely, and there was some purulent expectoration, which had a foul odor; examination of the sputum showed numerous pus organisms, but no tubercle bacilli or pneumococci were found.

She was advised to continue the tonic and hygienic treatment, and about October 1st she resumed her work, being in very good health.

Therapeutical Notes.

Creosote in Ozæna.—Ferrari, according to the *Riforma medica* for January 10th, recommends:

1. $\frac{1}{2}$ Creosote, $\frac{1}{2}$ of each equal parts.
Glycerin, $\frac{1}{2}$

And—

2. $\frac{1}{2}$ Creosote 75 grains;
Alcohol at 70 per cent. 150 "
Glycerin 600 "

For application on alternate days. If necessary, the cure is completed with the galvano-cautery.

The Treatment of Recurrent Epistaxis.—According to the *Riforma medica* for January 10th, Rendu recommends:

- $\frac{1}{2}$ Antipyrine $7\frac{1}{2}$ grains;
Tannin 15 "
Powdered sugar 150 "

To be used locally.

Subcutaneous Injections of Lecithin and Yolk of Egg in Infantile Anæmia and Marasmus.—Muggia (*Padiatria*, October, 1898; *Centralblatt für die gesammte Therapie*, January, 1899) recommends the use of a preparation made by adding to the yolk of a fresh hen's egg, in a sterilized capsule, one sixth of its weight of a seven-and-a-half per cent. solution of sodium chloride, stirring the mixture with a glass rod, and filtering

through absorbent gauze. From one to ten cubic centimetres are injected, generally in the lumbar region. The injections do not cause irritation or albuminuria. No result must be expected until twenty injections of at least five cubic centimetres each have been given.

A Mixture for Colic.—The *Riforma medica* for January 7th gives the following formula:

- $\frac{1}{2}$ Chloroform 8 parts;
Deodorized tincture of opium ... 6 "
Camphor 1 part;
Oil of cajuput 8 parts;
Water 200 "

M. S.: A teaspoonful every hour.

An Ointment for Granular Conjunctivitis.—Bloebaum (*Deutsche Medicinal-Zeitung*, January 23d) reports having observed decided benefit from the use of the following ointment in all stages of the disease:

- $\frac{1}{2}$ Copper sulphate, $\left\{ \begin{array}{l} \text{each} \dots\dots\dots 1 \text{ part;} \\ \text{Salicylic acid,} \\ \text{Cocaine,} \end{array} \right.$
Vaseline 100 parts.

M.

"Iodothyrein."—This substance, more properly called *thyroidin*, is the subject of a long article, by Lancereaux and Paulsco, the publication of which is begun in the *Journal de médecine interne* for January 1st. The authors deal more particularly with the effects of the remedy in such so-called "rheumatismal" affections as chronic rheumatism, gout, arteriosclerosis, vasomotor and trophic disturbances of the extremities, and scleroderma. They give the history of a case of generalized scleroderma in a young woman. She was much improved after four months' use of the remedy, which was to be continued.

The next case was that of a woman with "herpetism" and vasomotor disturbances of the limbs. The slightest exposure to cold caused blanching of the fingers and toes. Under the influence of thyroidin this trouble was much improved, and the profuse sweats and salivation with which the patient was also affected subsided entirely.

The third and fourth cases were those of men with "herpetism," chronic rheumatism and gout, generalized arteriosclerosis, hypertrophy of the heart, and renal sclerosis. Both were benefited in many respects by the treatment.

For Cocaine Poisoning.—The *Riforma medica* for January 21st attributes the following to Häetlin:

- $\frac{1}{2}$ Nitrite of amyl, $\frac{1}{2}$ of each, equal parts.
Spirits of wine, $\frac{1}{2}$

To be used by inhalation.

[We should advise great caution in the use of this remedy, only four or five drops being used at first, and the condition carefully watched.]

A Mixture for Coryza.—According to the *Riforma medica* for January 17th, Malbec recommends:

- $\frac{1}{2}$ Extract of hyoscyamus 24 grains;
Iodide of potassium, $\left\{ \begin{array}{l} \text{of each} \dots\dots\dots 30 \text{ " } \\ \text{Bicarbonate of potas-} \\ \text{sum,} \end{array} \right.$
Extract of hyoscyamus 75 "
Anise water 1,800 "

M.

A table-spoonful every four hours.

FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, FEBRUARY 25, 1899.

THE SERUM TREATMENT OF HOG CHOLERA AND
SWINE PLAGUE.

WE have frequently had occasion to commend the work done in the biochemical laboratory and in other fields under the supervision of Dr. Sahnon, the chief of the Bureau of Animal Industry. The importance of this work can not be overestimated, either in connection with the impediments that are still continually set up against American meat in certain European markets or as related to the home consumption of western beef and pork. An idea of the immensity of the interests involved in "animal industry," so far as food products are concerned, may be got by perusing a pamphlet lately issued by the bureau on *The Serum Treatment of Swine Plague and Hog Cholera*, prepared by Dr. E. A. de Schweinitz, with the collaboration of Dr. Marion Dorset and Dr. E. C. Schroeder. It is estimated, according to these gentlemen, that the State of Iowa alone loses \$15,000,000 annually in the loss of swine from disease—practically, we take it, from hog cholera and swine plague—\$11,000,000 of which might be saved at an expense to the farmer of not more than fifteen cents for each animal treated with the curative serum.

It can hardly be questioned, in the light of the bureau's investigations, that hog cholera and swine plague are essentially distinct diseases, although they present features of similarity which often render a diagnosis exceedingly doubtful in cases in which recourse is not had to bacteriological tests, and that resort obviously is in many instances out of the question, at least for the time being. Blood examinations resembling in a general way the employment of Widal's test for typhoid fever in the human subject, as has been suggested, might perhaps, says Dr. de Schweinitz, be useful in determining the character of diseases among swine in the field in a quicker way than would be possible if it was necessary always to work out the nature of the culture. While, however, Dr. Dawson, of the Division of Animal Pathology, has found that the majority of such blood examinations agree with the culture tests, in a few instances the reaction proper to hog cholera has been observed in blood taken from animals

that had undoubtedly died of swine plague, although they might have had in addition a slight infection with hog cholera. The two diseases, it thus appears, may coexist in the same animal.

In view of these difficulties of ready diagnosis, the bureau has felt the importance of endeavoring to produce a serum that would be efficacious against both diseases, and experiments have been carried on with that end in view. It had been shown, says Dr. de Schweinitz, that the serum prepared for the purpose of curing hog cholera was useful in protecting small animals from hog cholera only or in curing them of that disease only, and that the swine-plague antitoxine was efficient against swine plague only. Nevertheless, it had been shown that, if animals infected with hog cholera were treated with a mixture of the two antitoxines, they generally responded to the treatment a trifle more promptly than those treated with the hog-cholera antitoxine alone. Efforts were made, therefore, to establish in one and the same animal a serum that would prove effective against both diseases. In order to accomplish this, injections of hog-cholera cultures and swine-plague cultures or their products, alternately or together, were administered to the animals that were to serve as the source of the desired product, the doses being increased gradually until enough had been used to impart the necessary properties to the serum. In this way a serum was obtained which was slightly efficient against both diseases, but it was more active in checking swine plague than in checking hog cholera. Moreover, the animals treated did not thrive. There were good reasons, then, for turning to the simpler plan of furnishing a mixture of hog-cholera antitoxine and swine-plague antitoxine, and that is what the bureau is now doing. Nevertheless, the following statements are interesting: "The work, however, indicated the possibility of perhaps producing in the same animal a serum which may be specific for two distinct diseases. Experiments are being made now to ascertain to what extent this principle can be utilized in connection with other diseases of men and animals, especially tuberculosis."

Confidence in the efficiency of the mixed serum does not rest solely on laboratory experiments. A good deal of field work has been done in Page County, Iowa, under the direction of Dr. Dorset and Dr. McBirney, during the years 1897 and 1898, and check herds have been used, so that there can be no caviling as to the result—a great reduction of the mortality—having really been due to the use of the serum. That being the case, Dr. de Schweinitz is amply warranted in suggesting co-operation by certain States in this part of the work done by his bureau.

THE DISQUIETING FREQUENCY OF CRIMINAL ABORTION.

If we may judge from the tenor of our exchanges received from all parts for many months past, the widespread frequency of criminal abortion must give rise to considerable disquietude. When pregnancy is the result of illicit relations it is not, perhaps, so much a matter of surprise as of concern that criminal measures should be resorted to for its premature termination; but when, as is undoubtedly often the case, it occurs among respectable married women, who are often, moreover, in other respects of high moral character, great natural refinement, and culture, it suggests the need of a search for the causes underlying this blunted sense of right and wrong. The *exposé* recently made in England shows that outside of those who use or submit to operative interference for the procuring of abortion, there is a large and lucrative trade effected by nostrum dealers in abortifacients, often, no doubt, useless for the purpose for which they are sold, but none the less indicative of the attitude of mind on the subject of abortion among the vast *clientèle* of women who cause the business to pay.

The first and primal error, leading to conditions which ultimately suggest the crime of abortion, we think, lies in a total misconception of the real nature of the sexual act and its relation to "love." Two views only are commonly admitted. In the public mind it is with the vast majority a means of purely sense gratification, which is legitimized by "marriage." Marriage may be described as a social, religious, or social-religious compact, whose conditions and method of ratification vary in different races, religions, nationalities, and geographical areas, but the one point of which, common to them all, is that it conveys a license to a man and a woman to indulge in sexual relations without any public hindrance or social stigma attaching thereto; while such hindrance is effected and such stigma does attach to the same act between the same people, if publicly known, unless they have previously entered into that public contract under whatever conditions the local sentiment prescribes.

The other view is that of the social economists, who regard the performance of the sexual act as mainly and primarily for the procreation of the race. An article in the *Medical Press and Circular*, quoted by the *Cincinnati Lancet Clinic* for January 28th, on "The Marriage of Ovariectomized Patients, and referring to a recent law trial in this country in which a husband sued for divorce on the ground that his wife had prior to her marriage been the subject of oophorectomy, of which

fact he was not duly informed, gives frank expression to this view of the sexual relations in the following words: "We know of no authorized view of marriage other than that it is an institution for the procreation of children, and for the vast majority of persons this is, we presume, the ultimate object of the self-imposed sacrifice of sexual liberty."

Now, while we quite indorse the opinion expressed in the article quoted, that the fraud perpetrated by concealing the fact of a known incapacity for motherhood, undoubtedly one of the great reasons for the marriage relation, is a just and reasonable ground for the annulment of the marriage bond, we feel bound to protest against a view of the sexual relations which would reduce the glorified companionship of matrimony to the principles of a stud farm. We hear a great deal in these days about the "revolt of woman." With her awakening intellectual power, she is scarcely likely to remain content with a view of the greatest relationship of life which affords her the alternative of a choice between the position of a licensed handmaid of lust and the functions of a brood mare.

Neither of the views above quoted is in our opinion consistent with the ideal of love. Dr. George F. Butler, in a very thoughtful article, read before the Physician's Club of Chicago and published in the *Chicago Clinic* for January, on *Sexual Desire as Influenced by Religious Emotions*, emphasizes by admirably selected quotations the essential relation and analogy between sexual desire and religious feeling. He refers in illustration to the almost sensual expression of religious manifestations of an undoubtedly spiritual character among certain religious enthusiasts. This mode of expression seems easily explicable to us. The true idea of love is an earnest yearning for the most complete and intimate union, harmony of vibration, and mutual absorption attainable between two beings each of whom is both the lover and the beloved. In pure spirit the mode of union would be purely spiritual; in a solely material existence it would be purely sensual; in man it partakes of both in direct proportion to the balance between the physical and spiritual natures of the individual.

Are women as (physically) passionate as men? is a question often asked. We have studied this question extensively, and we must answer "yes" and "no." Women are ready, normal women we mean, to yield themselves wholly to the man they love, and to exalting as they do the inner grandeur of the act. But when they at last sadly and sorrowfully recognize the essentially sensual character of man's nature, and, even when he is genuinely attached to his partner therein, that which

should be to them the cup of sweetness often becomes bitter as wormwood.

In the act of sexual congress the properly balanced human being seeks such complete and perfect contact and union of his threefold nature with his mate as, we say it with all due reverence and without offense, the devout Christian of whatever denomination seeks intimate union for his spiritual nature with the Great Fount of all Pure Spirit through sacramental communion. The act of sexual union, therefore, which is undertaken solely for the production of a certain physical sensation is as impure and lustful, whether the parties have acquired a legal right to perform it or not, as an act of communion would be unholy in the Christian if done from a desire to appease hunger with the material bread, or to gratify the palate with the sensuous flavor of the wine, no matter though the act were done with all due observance of the rites and ceremonies prescribed by the religious body to which the individual happened to belong.

Now, in many people, such an exaltation of emotional desire as we consider should be the real motive of the act of sexual congress is often lacking; whence it follows that, speaking of a large number of people—and we refer only to the married in this connection—they must frequently transgress in an unworthy act of sexual communion. The upshot of this is likely to be a blunting of the moral sensibilities as regards the eventualities of such congress, and moreover the transmission of an excessive sensuality to the progeny.

From the social side the difficulties which are placed in the way of the mating of young people in whom the real higher emotion exists lead not infrequently to an "illicit" intercourse. To the artificial conditions which society imposes upon a young couple, such as the necessity for "keeping up an establishment," magnificent or humble in proportion to the previous social status of the subjects (whereas the girl would probably otherwise remain supported according to her station by her parents, while the man would have an income which sufficed only moderately well enough for him without social obligations to perform), must be added the small wage attendant on labor of whatever kind as compared with the large profits that accrue to the exploiter of his labor by means of his accumulated capital.

To these difficulties and obstacles the tendency of the present day is to add certain others, such as we referred to in an editorial on *The Sterilization of Women* in our issue for January 28th, on social economic ground for the benefit of the race, and utterly regardless of the rightful emotions and impulses of the individual. Hence follow illicit union (which is by no means neces-

sarily lustful in itself, though it probably arises from lust rather than love in the large majority of cases) and possibly an unexpected and unwelcome pregnancy entailing social outlawry unless obviated. The result is abortion, regarded by the distracted sufferers as the lesser of two evils.

When the congress is the result of lust, whether among the married or unmarried, pregnancy is likely in either case to prove unwelcome; and the blunted sensibilities to a higher ideal which are occasioned by the continual crime against Nature of dwelling on the "outward and visible sign" to the exclusion of the "inward and spiritual grace" or thing signified, viz., complete contact, union, and mutual absorption of two human beings in their perfect nature in all its component parts, mental, emotional, and physical, are not conducive to an adequate appreciation of the criminality of abortion.

The idea of lust as applied to normal sexual relations between married people may possibly strike many as strange. But we believe that in the want of general recognition of this fact lies the secret of the evil. A more thorough understanding and appreciative practice of actual purity, which is a matter of motive, not of act, among the married, together with the proper and progressive enlightenment of their children on lines similar to those suggested in our articles on *The Ethics of Adolescence*, would, we think, change the entire public estimate of marriage; and, by removing social and other impediments to the lawful expression of the imperious emotion of love, would at least relegate criminal abortion to the class of the essentially depraved.

MINOR PARAGRAPHS.

THE RESPONSIBILITY OF THE MEDICAL PRACTITIONER.

IN our issue for July 2, 1898, we published an editorial on *Actions for Malpractice*. A very important decision bearing on the subject of such actions was, we learn from the *Lancet* for January 28th, recently given in the Queen's Bench Division of the English High Court of Justice by Mr. Justice Mathew. A carpenter had sustained a fracture of the right leg, which was treated by a local doctor, with the result of five eighths of an inch shortening.

The cause of complaint was that the doctor had treated the patient as though only one bone of the leg was broken, whereas a subsequent X-ray photograph proved that both had been fractured. One medical man pronounced the treatment inadequate under the circumstances, while several others maintained that it was quite suitable, and the *Lancet* itself, while necessarily admitting the doctor's error in diagnosis, says: "The treatment for a fractured tibia is practically the same as that for both bones of the leg, therefore the defendant was not injured by the wrong diagnosis." Mr. Justice Mathew held in this case that medical men were not

responsible for errors of judgment if they honestly tried to do their best; and this the *Lancet* describes as "a very sensible finding." We think so, too, always provided that the error is not such as to show gross incompetence or ignorance of things which a practitioner of average intelligence ought to know. It is satisfactory to learn that the jury found for the defendant.

A BIT OF HASTY CRITICISM.

We have received from a Chicago physician a postal card bearing the following message: "Your leading editorial in last Saturday's *Journal* (February 11th) noticed; hence I smiled when a little further on, page 212, sixteenth line from bottom of first column, I read: 'ideas they have got about on the serious effects.' If our correspondent will 'look again,' he will find that the passage really reads 'ideas that have got about,' etc. Moreover, the whole thing is in quotation marks.

COMMERCIAL TRAVELING AS A CAUSE OF NEURASTHENIA.

GRANHOLM (*Finska Lakaresällskapet Handlingsgar*, October, 1898; *Archives de neurologie*, January, 1899) thinks that the exciting life of a commercial traveler is very likely to lead to neurasthenia, not only from the irregularities incident to such a life, but also from the fact that the traveler has constantly to deal with great numbers of strangers. He recommends isolation in the treatment.

A HAIRPIN IN A HERNIA.

In the *Montpellier médical* for January 23d de Bonville records a case in which, in performing Championnière's radical operation for inguinal hernia, he found a hairpin in the sac. The patient said that he had thrust it "into his belly" to keep the hernia reduced.

MR. HAVELock ELLIS'S BOOK ON SEXUAL INVERSION.

The *Southern Medical Record* for January quotes a generally excellent article on this subject from the *Medico-legal Journal*. The article, however, closes as follows: "There can be no doubt that Mr. Ellis made a serious mistake in selecting his publisher. Mr. Bedborough may have been a dealer in obscene books, and *persona non grata* with the court or the authorities. It is stated that he has published a magazine devoted to the propaganda of unconventional views upon marriage, and the book of Mr. Ellis may have been, in the judgment of the authorities and the recorder, tarred with the same stick with Mr. Bedborough's other publications—we do not know. Even were this so (which was, as we think, a grave error on the part of Mr. Ellis), it would not change the character of the unjust accusation made against the work by the recorder, but would bear in mitigation and explanation of the judicial utterances; but the lesson to Mr. Ellis, and to writers generally, would remain, that authors, as well as men, are known and judged by the company they keep, and Mr. Ellis, like poor Tray, have been judged by reason of his unfortunate environment." We know nothing of Mr. Bedborough or his views, but we would remark that of the publication of "unconventional" views on marriage or any other subject, when they are honestly held, we should

deemed reprehensible, then the sooner we give up all idea of progress, abandon all research, and relinquish all philosophic scholarship and investigation into social, moral, or economic problems, and settle down to stagnation, the better. We may ask if Washington and his colleagues had indorsed that opinion would there now have been any United States of America?

THE TOXIC EFFECTS OF BORIC ACID.

EVANS (*British Medical Journal*, January 28th) reports a case in which, after about three weeks' use of boric acid in increasing doses of from ten to twenty grains three times a day, for cystitis, an erythematous rash appeared on the neck, face, and head, and was followed by some subcutaneous oedema and a fine scaly dermatitis. The salivary glands began to enlarge and subsequently the man became perfectly bald. It was six weeks before there was any new growth of hair. The author has observed the milder of these effects in a number of other cases, but has always been able to prevent baldness by stopping the administration of the drug.

DR. BARKER ON THE NEURONES.

For a number of months past we have published from time to time exceedingly valuable articles on The Anatomy and Physiology of the Nervous System and its Constituent Neurones, by Dr. Lawellus F. Barker, of the Johns Hopkins University. These articles, together with a considerable amount of added matter, our readers will be glad to learn, are soon to be published in book form.

THE PAY OF CORONERS' PHYSICIANS.

The bill that has recently been introduced into the Assembly of the State of New York having for its object the raising of the annual salaries of the coroners' physician ought to be facilitated in its progress toward enactment by the fact of its having been introduced by Dr. Henry, one of our assemblymen. We have before advocated an increase of pay for the hard-worked officials in question, and we hope Dr. Henry's bill will become a law.

A WOMAN WITH A PENIS.

In the *Centralblatt für Gynäkologie* for February 1th Neugebauer reports the case of a Jewish woman, twenty-seven years old, who applied for employment at a wet-nurse agency seven days after having given birth to a child. In the examination it was found that she had what appeared to be a penis springing from the perineum. It was not quite two inches long when flaccid, but on manipulation it became erect and measured rather more than two inches. It was provided with a well-defined glans, which was partly covered by a prepuce.

ITEMS.

An Interesting Point in the History of the Orthopedic Corset. On January 27th Dr. A. M. Phelps, of New York, read before the Royal Society of Medicine and Surgery a paper on "The Corset of the Future." The paper dealt with the history of the corset from the time of the Spaniards and the French. It was a very interesting and valuable paper, and it was well received by the audience. The paper was published in the *British Medical Journal*, February 28th, 1899. It was a very interesting and valuable paper, and it was well received by the audience. It was published in the *British Medical Journal*, February 28th, 1899. It was a very interesting and valuable paper, and it was well received by the audience.

cussion. Among the speakers was Dr. Stuart McGuire, who said that the subject of Pott's disease was one of peculiar interest to him, as he had been the victim of the disease during childhood; that he had been a patient of Dr. Lewis A. Sayre's; that he had been the subject of many experiments, and that he believed he was the original person upon whom the plaster-of-Paris jacket was applied; that, although twenty-five years had elapsed, he could remember how Dr. Sayre placed him face downward across his knees and by separating his legs and producing extension relieved pain and reduced deformity. This was the inception of a principle now carried out by suspension. He remembered how Dr. Sayre placed his broad hands on either side of the spinal column and, by gentle pressure, maintained the correction secured and gave support and immobilization to the back. This was the inception of the principle now carried out by the plaster cast. Dr. McGuire said that the first attempt at the practical application of the brace consisted in laying him upon a table and producing extension by manual traction on his head and feet and then the application of alternate layers of squares of flannel and wet plaster to his back. This formed a "turtle shell," which was held in place by circular turns of a cotton bandage.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the three weeks ending February 18, 1899:

DISEASES.	Week ending Feb. 4.		Week ending Feb. 11.		Week ending Feb. 18.	
	Cases.	Deaths.	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	12	5	11	5	15	1

The Tri-State Medical Association of Mississippi, Arkansas, and Tennessee and the "Osteopaths."—At the annual meeting, held in Memphis on December 20th, 21st and 22d, the sense of the meeting was expressed as follows:

Whereas, The medical laws of the various States have been so perverted by political influences as to give legislative sanction to grotesque, ignorant, and dangerous sects of pretenders and charlatans; and

Whereas, The privileges granted to one of the most outrageous aberrations—namely, the so-called osteopaths, constitute a disgrace to the States in which the "osteopaths" are legally entrenched; and

Whereas, a certain William Smith, osteopathist, having been roundly denounced, together with his sect, by Parke, Davis, & Co., and the *Medical Age*, now brings suit against both for twenty five thousand dollars damages; therefore

Be it Declared the sentiment of the Tri-State Medical Association of Mississippi, Arkansas, and Tennessee that Parke, Davis, & Co. and the *Medical Age* are entitled to the sympathy of its members and of all medical practitioners; that we wish and expect them to enjoy a complete triumph in repelling the legal assault; and that where ever a powerful house takes a bold stand in opposition to quackery it promotes the interests of legiti-

mate and honorable medicine and the welfare of humanity.

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, cholera, and plague were reported to the supervising surgeon-general of the United States Marine-Hospital Service during the week ending February 18, 1899:

Small-pox—United States.

Denver, Col.....	Nov. 2-Feb. 8.....	23 cases.
Washington, D. C.....	Feb. 7.....	6 "
Dana, Ind.....	Feb. 8.....	1 case.

--------------------	-----------------	-------------

A Foreign Body in an Appendicular Abscess.—Dr. P. H. Fithian, of Springfield, Illinois, surgeon in charge

of the Wabash Employees' Hospital, writes to us as follows: In the *New York Medical Journal* for January 28th I notice Dr. Phelps's report of a case of appendicitis in which the appendix was found to contain a minute piece of bone.

This article calls to mind a case that I had in July last, which I think may be of interest. Briefly, it is as follows: C. H. M., a freight brakeman, aged twenty-eight, with no history of a previous attack, began to feel badly on Saturday, June 25, 1898, at noon. About noon the following Monday he was seized with violent pain in the region of the appendix, and immediately took to his bed in the caboose, and summoned a physician, who did not reach him until 5.30 that evening. He diagnosed the case as appendicitis, advised the man to go to hospital at once, and gave him half a grain of morphine by the mouth; but this did not influence the pain, and that night the patient got no sleep. The next day he was admitted into the hospital at noon, having come a distance of forty miles. For the next few days pain was controlled by morphine administered hypodermically, the bowels were moved every day or two with magnesium, and hot applications were kept over the seat of pain. On July 6th I was of the opinion that there was an abscess which should be incised, and called Dr. J. A. Prince in consultation, who advised an operation. The next day the abscess was incised, evacuated, irrigated, and packed lightly. It was flushed out every day thereafter, and during one of these flushings, on July 11th, Dr. Prince and my house-surgeon, Dr. Fisher, being present at the time, I noticed within the cavity of the abscess a foreign body of some kind, which I removed with a forceps and found to be a piece of solder, quite thin, triangular in shape, and weighing eight grains.

The man afterward stated that he had for some time been very fond of canned raspberries, frequently calling for them at the eating houses along the road, and I doubt not that here is the clue to the little piece of solder which lit up his attack of appendicitis. I will add that he made an uneventful recovery, resuming his duties as brakeman the following September, and continuing thereat until this week, when he returned to hospital for treatment for tinea tonsurans, thus giving me the opportunity of completing the history of the case just when I most wished for it.

A Congress for the Suppression of Tuberculosis is to sit in Berlin from the 24th to the 27th of May, under the presidency of the Herzog von Ratibor and Dr. von Leyden. Particulars may be learned by addressing the secretary-general of the organization committee, Dr. Pannwitz, No. 2 Wilhelm Platz, Berlin, W.

The Buffalo Academy of Medicine.—At the last regular meeting of the Section in Pathology, on Tuesday evening, the 21st inst., Dr. H. R. Hopkins opened a discussion on the following papers: Intraocular Tumors, by Dr. B. H. Grove; and The Pathology of Alcoholism, by Dr. J. W. Grosvenor.

The Atlantic County (New Jersey) Medical Society.—Officers were recently elected as follows: President, Dr. A. D. Cuskaden; vice-president, Dr. W. Reynolds; secretary and treasurer, Dr. W. Edgar Darnall; reporter, Dr. E. Marvel.

The Atlantic City Academy of Medicine. Officers were recently elected as follows: President, Dr. W. B. Stewart; vice-president, Dr. W. Edgar Darnall; secret-

tary and treasurer, Dr. W. Reynolds; corresponding secretary, Dr. J. B. Thompson.

The St. Louis Medical Society.—At the last regular meeting, on Saturday evening, the 18th inst., the following papers were presented for discussion: The Surgical Treatment of Trifacial Neuralgia, with a Report of a Case of Removal of the Gasserian Ganglion, by Dr. N. B. Carson; The Pathology of Trifacial Neuralgia, with a Microscopic Demonstration on the Screen of the Normal and Diseased Gasserian Ganglion, by Dr. Ludwig Bremer; and A Report of a Case of Removal of the Gasserian Ganglion, by Dr. H. H. Mudd.

The Late Dr. McGillicuddy.—At a special meeting of the corps of professors of the New York School of Clinical Medicine, held on January 20, 1899, the following resolutions were unanimously adopted:

Whereas, It becomes our sad duty to chronicle the death of our late esteemed colleague, Dr. T. J. McGillicuddy, which untoward event occurred on the 17th day of January, 1899; therefore be it

Resolved, That, while recognizing in this sudden and unexpected dispensation the hand of an all-wise Providence, we nevertheless appreciate the importance to the institution of the loss of one of its devoted friends.

Resolved, That we, his associates, express deep regret at the loss of our esteemed colleague, whose interest in all that pertained to the advancement of medical science won our esteem and admiration.

Resolved, That the death of Dr. McGillicuddy deprives this community of one of its most useful citizens and the medical profession of a representative who always labored earnestly to uphold its best interests.

Resolved, That a copy of these resolutions be sent to his family and to the medical press of this city.

J. J. E. MAHER, M. D.,

Chairman,

J. J. MORRISSEY, M. D.,

Secretary,

Committee.

The Death of Professor Coats.—By the death of Dr. Joseph Coats, Glasgow University in particular and the British Medical profession in general lose one of their brightest ornaments. As a pathologist, and especially as a teacher of pathology, he held high rank, and it was largely due to his efforts that the Pathological Institute, which was opened in 1896, was established on a firm and solid basis. He died in his fifty-third year from sudden collapse in the interval between the first and second stages of lumbar colotomy performed for relief from the effects of a malignant tumor in the region of the descending colon. His loss will be widely felt in the domain not only of his special science but of medical literature also; for besides his various works it was under his able editorship that the *Glasgow Medical Journal* thrived.

The Death of Dr. Ernst Julius Gurlt, the well known writer on fractures, is recorded by the *Wiener klinische Wochenschrift* as having taken place on January 20th. He was in his seventy-fourth year.

The Chicago Society of Internal Medicine.—At the last regular meeting, on Thursday evening, the 24th inst., the following papers were presented for discussion: Cardiac Rheumatism, by Dr. Joseph M. Patton; The Relations of Rheumatism and Chorea, by Dr. Robert B. Preble; and Where shall we seek for the Etiology of Patients? The Health Resorts of the West and Southwest,

by Dr. Frank E. Waxham. It is announced that the discussion on acute articular rheumatism will be concluded at the March meeting.

Complete Transposition of the Viscera.—In the *Archives des sciences médicales* for September and November, 1898, Dr. E. Nimovici and Dr. E. Juvara give a complete and detailed account with excellent illustrations of a case of transposition of all the viscera of the thorax and abdomen in a Roumanian aged thirty-two.

Change of Address.—Dr. Charles E. Denison, to No. 215 West Thirty-fourth Street.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the Two Weeks ending February 18, 1899:*

BERRYHILL, T. A., Passed Assistant Surgeon. Detached from the *New York* and ordered to the *Panther*.

BLACKWELL, E. M., Assistant Surgeon. Detached from the *Franklin* and ordered to the *Abarenda*.

BYRNES, J. C., Surgeon. Detached from the *Puritan* and ordered to continue duty at the Norfolk Navy Yard.

DRAKE, N. H., Surgeon. Detached from the *Minneapolis* and ordered home to await orders.

HEKNDON, C. G., Surgeon. Ordered to temporary duty on the *Richmond*.

KINDLEBERGER, C. P., Passed Assistant Surgeon. Promoted with relative rank of lieutenant, junior grade.

McCULLOUGH, F. E., Assistant Surgeon. Detached from the Naval Hospital, Mare Island, California, and ordered to the *Nero*.

PAYNE, J. H., Assistant Surgeon. Detached from the *Marcellus* and ordered to temporary duty on the *Franklin*.

RIGGS, C. E., Passed Assistant Surgeon. Detached from the *Topeka* and ordered to the *New York*.

SHUGRUE, D. A., Assistant Surgeon. The order of February 4th, detaching him from the *Abarenda* and ordering him home, is modified, and he is ordered to temporary duty on the *Topeka*, and, when that vessel arrives at Boston, he is detached and ordered home.

SHUGRUE, D. F., Assistant Surgeon. Honorably discharged from the service of the United States.

STEFF, J., Assistant Surgeon. Detached from the *Independence* and ordered to the Naval Hospital, Mare Island, California, for temporary duty.

WESTWORTH, A. R., Surgeon. Promoted, with relative rank of lieutenant.

YORNG, L. L., Passed Assistant Surgeon. His leave of absence on account of sickness is extended three months.

The following order was issued from the headquarters of the army, February 4th: ROSS, JOHN W., Surgeon, United States Navy, retired, having been assigned to duty under the War Department, will proceed from Clarksville, Tennessee, to Havana, Cuba, and report in person to the commanding general, Division of Cuba, for assignment to duty.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 4 to February 11, 1899:*

BRENING, CHARLES, First Lieutenant and Assistant Surgeon, is honorably discharged from the service of the United States.

BUSHNELL, GEORGE E., Major and Surgeon, is detailed as a member of the board of survey appointed to meet at the War Department to investigate the loss of certain hospital and commissary funds during the storm and tidal wave at Fernandina, Florida, October 2, 1898.

EVERTS, EDWARD, Captain and Assistant Surgeon, is relieved from further duty at Fort Apache, Arizona, and will proceed to San Francisco for duty.

GANDY, CHARLES M., Major and Chief Surgeon, is relieved from further duty at the Josiah Simpson Hospital, Fort Monroe, Virginia, and will proceed to Fort Slocum, New York, for duty.

GIBSON, ROBERT J., Major and Surgeon, is relieved from duty at Anniston, Alabama, and will return to his proper station, Fort Meade, South Dakota.

GREENLEAF, HENRY S., First Lieutenant and Assistant Surgeon, will proceed to Washington Barracks, D. C., for duty.

HARRIS, HENRY S. T., Major and Brigade Surgeon, is detailed as a member of the examining board appointed to meet at Huntsville, Alabama, *vice* McCULLOUGH, CHAMPE C., Captain and Assistant Surgeon, who is hereby relieved.

LYON, GEORGE E., Major and Surgeon, is honorably discharged from the service of the United States.

MEARNS, EDGAR A., Major and Chief Surgeon, is relieved from his present duties, and will proceed to Fort Adams, Rhode Island, for duty.

MUNSON, EDWARD L., Captain and Assistant Surgeon, is detailed as a member of the army retiring board appointed to meet in Washington at the War Department, for the examination of such officers as may be ordered before it.

SWIFT, EUGENE L., Major and Brigade Surgeon, is honorably discharged from the service of the United States.

WETHERILL, HENRY E., First Lieutenant and Assistant Surgeon, is detailed as a member of the examining board appointed to meet at Huntsville, Alabama, *vice* STONE, JOHN H., First Lieutenant and Assistant Surgeon, who is hereby relieved.

Society Meetings for the Coming Week:

MONDAY, February 27th: Medical Society of the County of New York; Lawrence, Massachusetts, Medical Club (private); Cambridge, Massachusetts, Society for Medical Improvement; Baltimore Medical Association.

TUESDAY, February 28th: New York Dermatological Society (private); Metropolitan Medical Society, New York (private); Buffalo Academy of Medicine (Section in Obstetrics and Gynecology); Rome, N. Y., Medical Society; Boston Society of Medical Sciences (private); Richmond, Virginia, Academy of Medicine and Surgery.

WEDNESDAY, March 1st: New York Academy of Medicine (Section in Public Health); Society of Alumni of Bellevue Hospital; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond, N. Y. (New Brighton); Penobscot, Maine, County Medical Society (Bangor); Bridgeport, Connecticut, Medical Association.

THURSDAY, March 2d: New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, N. Y.; Boston Medico-psychological Association; Obstetrical Society of

Philadelphia; United States Naval Medical Society (Washington); Medical Society of City Hospital Alumni, of St. Louis; Atlanta Society of Medicine.

FRIDAY, March 3d: Practitioners' Society of New York (private); Clinical Society of the New York Post-graduate Medical School and Hospital; Baltimore Clinical Society.

SATURDAY, March 4th: Manhattan Medical and Surgical Society, New York (private); Miller's River, Massachusetts, Medical Society.

Births, Marriages, and Deaths.

Married.

BENNETT—MATTISON.—In Brooklyn, on Friday, February 10th, Ensign Ernest L. Bennett, United States navy, and Miss Mabel Chester Mattison, daughter of Dr. J. B. Mattison.

HOLMES—BOISE.—In Berlin, Germany, on Tuesday, February 14th, Dr. Edwin Holmes, of New York, and Miss Frieda Boise.

KOONZ—TOFFEY.—In Jersey City, on Tuesday, February 14th, Dr. Albert E. Koonz, of New York, and Miss Jennie Rodger Toffey.

SHEA—WEEKS.—In New York, on Tuesday, February 14th, Dr. Dennis L. Shea and Miss Anna J. Weeks.

Died.

HOVEY.—In Rochester, N. Y., on Sunday, February 12th, Mrs. Marilla D. Hovey, wife of Dr. Bleecker L. Hovey.

HUNTINGTON.—In Boston, on Monday, February 13th, Dr. Alfred T. Huntington, aged thirty-one years.

MEEKER.—In Leconte, Louisiana, on Sunday, February 12th, Dr. Samuel F. Meeker, in the sixty-fourth year of his age.

ROSE.—In Roxbury, Massachusetts, on Thursday, February 9th, William A. Rose, son of Dr. George S. Rose, United States army.

SIZER.—In Brooklyn, on Thursday, February 16th, Mrs. Georgiana Mitchell Sizer, wife of Dr. Nelson B. Sizer, in the forty-ninth year of her age.

STEWART.—In Shippensburg, Pennsylvania, on Friday, February 10th, Dr. Robert C. Stewart.

TUFTS.—In Dover, New Hampshire, on Sunday, February 12th, Dr. Charles A. Tufts, aged seventy-seven years.

THE LAW IN ITS RELATIONS TO PHYSICIANS.

By ARTHUR N. TAYLOR, LL.B.

VII

CONTRACT OF PHYSICIAN WITH PATIENT

(Continued from page 26.)

Contracts to Follow Established Modes of Practice.

—The physician and surgeon also implicitly contract

with his patients that in his treatment of them he will comply with the established modes of practice.*

Such a method or system of treatment must, however, be upheld by a consensus of opinion among members of the profession before the practitioner is bound to accept and follow it in his practice.*

There are probably many cases in which the physician and surgeon possessing the skill and ability required by law can not by the exercise of due care and diligence determine the particular disease or condition from which the patient is suffering. In such case, if he uses ordinary care and skill, and by the exercise of his best judgment determines upon a particular disease, and then applies the recognized remedy or mode of treatment for that disease, he is fulfilling his contract with the patient and doing all the law requires of him in the particulars considered. But if he experiments with some other mode of treatment he does so at his peril. Justice Goddard, in the case of Jackson vs. Burnham, said: "In other words, he must be able in case of deleterious results to satisfy the jury that he had reason for the faith that was in him, and justify his experiment by some reasonable theory."⁴

Duty to Instruct Patient and Nurse.—It is also incumbent upon the physician and surgeon to give all reasonable and necessary instructions for the proper treatment and care of the particular disease or injury for which he is treating the patient; and should injury result from his failure to exercise this precaution he will be held to respond in damages.⁵ This obligation extends not only to giving instructions for the period during which the physician is attending the patient, but also for the period of convalescence immediately following. Therefore a physician should, upon dismissing his patients, carefully tell them what to avoid, and advise them to exercise that care which in his judgment is best calculated to restore their natural health and strength.⁶

The physician should not, however, be held to anticipate and advise against improbable conduct on the part of the patient. Where, for instance, a patient who is under the care of a physician at a hospital leaves the hospital without informing the physician of his intent so to do, it will be unjust to hold the physician to the duty of anticipating the patient's departure and advising him to remain.

Does not Contract to Cure.—Without a special contract to that effect the physician and surgeon is never considered as guaranteeing that he will effect a cure, or even benefit his patients.⁷ A physician may, however, enter into such a contract by express agreement providing that he shall be paid only in case he effects a cure, and such a contract, when entered into, will be binding though no definite sum is named as the compensation for performing the cure.⁸ When no such contract is agreed upon, the physician will, upon performance of the cure, be entitled to a reasonable amount for such services, to be determined in the ordinary manner.

⁷ Richards v. Whelan, 12 Cal. 2d 114, 115.

⁸ See, e.g., 10 Cal. 2d 114, 115; 12 Cal. 2d 114, 115; 14 Cal. 2d 114, 115.

⁹ See, e.g., 10 Cal. 2d 114, 115.

¹⁰ See, e.g., 10 Cal. 2d 114, 115.

Continuation of Attendance.—A physician may by special contract, when undertaking the treatment of a case, limit his attendance to a longer or shorter period, or may at any time during the treatment of the case discontinue his attendance by first giving reasonable notice of his intention so to do; but if he does not limit his attendance by express contract or give such reasonable notice of his intention to discontinue his visits, he is bound to continue his visits as long and as frequently as the requirements of the case may demand, and he is held to the use of ordinary care and skill in determining when his visits may be safely discontinued.*

Contagious Disease.—It is the duty of the physician, and he is impliedly contracts, to protect his patients in all reasonable ways from contagious and infectious diseases. If he himself has such a disease, and with knowledge of his condition visits his patients without apprising them of the fact, and thus communicates the disease to them, he is clearly guilty of a breach of duty. Moreover, it is his duty, in passing from patients who are afflicted with an infectious and dangerous disease to others who are not so affected, to take such precautions as experience may have shown to be necessary to prevent the communication of infection, and he will be held responsible for his failure so to do.† When the physician has effected a cure of a patient afflicted with a contagious or infectious disease, it becomes his duty to employ all proper and necessary means to disinfect the premises, and the law will protect him in fulfilling such duty, even though it may involve destruction of property.‡

Contract for Medical Treatment Includes Surgical Cases.—A physician who enters into a contract with a patient or with a third party, agreeing to give "medical" treatment or to "perform the duties of a physician" for a certain period of time, there being no express understanding regarding surgical cases, or nothing to show that it was clearly the intent that surgical cases should be excluded, will be required under the contract to perform surgical operations as well as to give general medical treatment during the period.§

Privileged Communications.—Last, but by no means least in importance, the physician contracts with his patients that he will preserve sacred and inviolable all knowledge which comes to him in a professional way. So sacred is this knowledge held that in many States the physician is not required to disclose the same in a court of justice without the patient's consent. Knowledge of this sort is technically known in the law as privileged communications. The questions arising under this privilege being many and varied, they are made the subject of a separate article.

Importance of the Foregoing Principles.—By way of general observation it may be said that the foregoing contracts and obligations implied on behalf of the physician form nearly the whole groundwork of the law regulating the subject of civil malpractice, and if the physician carefully remembers and applies this law he may hope to escape being required to face an injured patient

in a court of justice, and certainly to avoid being mulcted in damages.

(To be continued.)

Proceedings of Societies.

SOCIETY OF THE ALUMNI OF THE CITY (CHARITY) HOSPITAL.

Meeting of December 14, 1898.

The President, Dr. WALTER B. JOHNSON, in the Chair.

Multilocular Cysts of Both Ovaries.—Dr. GEORGE H. MALLETT presented specimens of multilocular cysts of both ovaries, and gave the following history: They were removed from a patient twenty-four years of age, married two years, who had her first child a year ago and a miscarriage six weeks ago. She began to menstruate at sixteen. She menstruated only once in two months until she was twenty-one years old, when she was married, and the menstruation then was regular until she became pregnant. In September she flowed for four weeks, and this was followed by a miscarriage. When she came under the speaker's observation he felt a large mass on the left side of the pelvis. She did not give any history of pain, but it was difficult to find the uterus, and he suspected ectopic gestation. When he opened the cavity, he found one ovarian cyst on the left side low down in the pelvis; the other was under the liver. The interesting point was, not the difficulty of diagnosis, for it was difficult to tell ectopic gestation unless the sac had ruptured, but the fact that the woman became pregnant twice with the ovaries in this condition, showing that women could conceive when the ovaries were in very bad condition.

The other specimen was a large cyst taken from a girl sixteen years and four months of age. She missed her menstrual periods four months after she came from abroad, and afterward noticed the enlargement. She had absolutely no pain and the family began to suspect pregnancy. The cyst was removed about three weeks ago. The pedicle was long.

Dr. BROOKS H. WELLS said it was rare to find cystic ovarian tumors of such an extremely irregular shape. Another remarkable thing was that the woman should conceive when there was apparently no normal ovarian tissue left. He believed in the advisability in many cases of leaving small bits of an ovary, if they were not absolutely diseased. A year ago last June he operated on a patient at the Polyclinic Hospital, removing from the right side an abscess which involved the ovary and tube. On the left side there was no pus, but there were a cystic ovary and a densely adherent tube. The ovary was removed, leaving only a tiny nodule, and the adhesions about the tube were broken up. Much to his surprise and gratification, the woman came back to the clinic last week four months pregnant. This result was most unexpected, as he had left the bit of ovary solely with the idea of lessening the nervous symptoms that might follow the premature menopause.

Dr. CLEMENT CLEVELAND said that in all his experience he had never seen two such specimens coming from the same woman and so unique. He spoke of the method that he employed in the ligation of the pedicle. He

§ Wetherell vs. Marion Co., 28 Iowa, 22; Clinton Co. vs. Ramsey, 20 Ill. App., 577.

had for a year and a half been using Dr. Skene's electric clamps on the pedicle for ovarian tumors and in pyosalpinx with great satisfaction. Dr. Skene had been experimenting for three or four years with this method, which was suggested to him by the old process of Dr. Keith, of Edinburgh, who used a hot iron, clamping and burning thoroughly, and reported that he never had a case of secondary hæmorrhage following its use. The speaker used the crude ones made a year and a half ago, but they had been improved since that time. The clamps were applied as an ordinary clamp would be. In the case, for instance, of an ovarian tumor with a pedicle, one might apply the clamp close to the uterus; then, if he had not the street current which he could modify by a transformer, use an ordinary battery with power enough to give six or seven amperes of electricity, carrying a heat of about 198° or 200° , so as not to burn the tissue, but bake or cook it, or rather desiccate it. These clamps were usually left on from two to three months; then the tumor was cut away and the clamps were slowly removed. If the heat had been uniformly applied, there was rarely any oozing. The stem, as it was cut off, appeared like a charred mass.

When the speaker first used this method he felt rather uneasy about his patients, but during the year and a half he had constantly used it he had never observed any secondary hæmorrhage. This process did away with the catgut or silk ligatures. The heat shut up the lymphatics; it was aseptic and antiseptic as well. On Saturday last he used it on a patient with carcinoma of the cervix, where it was difficult to find room to cut outside of the disease. The healthy tissue was clamped, the forceps applied, and the uterus removed in the usual way. This patient had been in bed for four days and had no pain whatsoever; she would have no idea herself, if she had not been told, that she had gone through a severe operation. The gauze packing had not yet been removed; he did not usually remove it till the sixth day. When he did remove it, he would give the patient a little chloroform, so that she would have no pain whatsoever. He thought if others would use the forceps, they would be as enthusiastic as he was. The tumors presented to the society could have been removed by the vagina if Dr. Mallett had known what they were, especially the multicellular which had a long pedicle, and by the electric clamp it could have been removed without being ruptured.

(To be concluded.)

Miscellany.

The Disagreeable Results of Gelatin Injections for Hæmostasis.—According to the *Therapeutic Gazette* for January 16th, it must not be lost sight of that Deguy tells us in the *Journal des pédiatres* of November 12, 1898, that the subcutaneous injection of gelatin solutions is capable of producing the following disagreeable symptoms: A condition of fever may develop, ranging from two to three degrees above normal, and this may last for a day or two. It is apt to be present in the

evening and not in the morning, and sometimes is accompanied by chills and insomnia. The local accidents which follow its injection may be divided into three classes: First, pain, due to the injection, of a burning character, which is increased by pressure; secondly, a diffuse redness of the skin or pseudo-inflammatory process, violaceous in appearance, which disappears for a moment on pressure and then immediately returns; thirdly, a diffuse induration of the tissues, having very much the same sensation as the induration due to anthrax. Usually this lasts a number of days.

Chloral Eruptions.—The *Therapeutic Gazette* for January 16th in an editorial says:

"Two theories have been advanced to explain these eruptions. One is that the drug produces an angioneurosis or vasoparalysis, probably by an action on the vasomotor centres. The other theory is that some of the chloral is eliminated by the glands of the skin, and in its elimination produces local irritation. According to Aviragnet, these eruptions may be divided into two great classes. In the first they appear in the presence of conditions of the nervous system characterized by exaggerated excitability, as, for example, chorea, insanity, tetanus, general paralysis, also in transverse myelitis and after operative shock. In the second class of cases they occur in instances in which there is retention of chloral in the system, as, for example, in acute and chronic enteritis, eclampsia, hepatic disease, advanced tuberculosis, and abdominal tumors. Then, too, it is well known that the simultaneous administration of alcohol with chloral often causes dermal manifestations, and hot drinks given with chloral, particularly if they are copious, are apt to produce such effects. Of course, in the cases where chloral is applied externally it produces a direct local irritant influence."

Seeing through the Nose.—M. Douliot (*Revue médicale; Gazette des hôpitaux*, August 21, 1897; *Revue internationale de rhinologie, otologie et laryngologie*, December, 1898) reports the case of a man who, as was the case with several others reported in the sixteenth and seventeenth centuries, learned to see through his nasal cavities after the successive loss of both eyes. The right eye had been lost in childhood; the other eye, as well as the nose, had been lost in a fall upon a stake. A year later he perceived that he was able to distinguish through the nasal aperture the light of day, and also brilliant objects placed beneath it. It is considered probable that the retina had been spared, and that there remained an opening of communication between the nasal fossae and the orbital cavity.

The Highest Causes of Mortality in the City of Mexico.—According to the *Boletín del Consejo superior de Salubridad* for December, 1898, out of 1,313 deaths occurring in the city of Mexico in the month of November, 125 are credited to tuberculous affections, 105 to acute bronchitis, 117 to pneumonia, and 212 to diarrhoea and enteritis. These are the only specified causes that reach triple figures, the next highest being gastro-enteritis, the stated cause of death in 61 cases.

A Simple Operation for Ingrowing Toe Nail.—Dr. J. G. MacCallum (*Massachusetts Medical Journal*, January) records a method of treatment which he tried first *in propria persona*, all the usual methods having failed. He says: At length the following course was pursued:

A triangular notch was made midway in the free edge of the nail, extending to its body. From the pointed margin of this notch a furrow was made, as near to the quick as possible, without penetrating it, through the middle of the root as far as the duplicature of skin; a piece of cork was then inserted under the nail, whose bulk was large enough to extend a few lines on either side of the notch, as well as to compactly fill, without uneasiness, the interspace between the skin and extremity. This completed the "operation."

In a few hours relief was marked, rapid improvement followed, and in a very short time it was quite evident that the cure was complete. The elevating tendency of the piece of cork caused the corners to be raised from the inflamed flesh, while at the same time the furrow through the centre allowed the nail to flatten and the burrowing edge of the ingrowing corner to eventually pass over and beyond the limited space of its former confinement. Thus, it is plain, all the indications of cure were fulfilled.

Since then he has pursued this plan of treatment alone in such cases, and in every one with unflinching success.

Schlatter's Case of Removal of the Stomach.—Schlatter (*Lancet*, November, 1898; *International Medical Magazine*, January) communicates his further observations on his case of complete removal of the stomach. The patient's weight has increased eighteen pounds and a half since the operation. Her general condition is excellent, and she is able to partake of ordinary diet without any inconvenience other than a feeling of pressure in the epigastrium and in both hypochondriac regions after a hearty meal. A quantity of milk amounting to ten fluid ounces and a half is quite capable of producing this feeling of pressure. Her digestive capacity can be judged from the following diet lists: January 17th: Milk, thirty-three fluid ounces; coffee, thirteen fluid ounces; three rolls; three eggs; soups, three fluid ounces and a half; fried sausage, four ounces; stewed apples, seven ounces; whortleberries, three ounces, and claret, seven fluid ounces. February 5th: Milk, eleven fluid ounces and a half; three rolls; three eggs; soup, four fluid ounces; sweetbreads, ten ounces and a half; cauliflower, seven ounces, and claret, seven fluid ounces. March 4th: Milk, ten fluid ounces and a half; coffee, seven fluid ounces; soup, four fluid ounces; roast veal, four ounces; carrots, fourteen ounces; four rolls, and claret, seven fluid ounces. Her animal food varied between roast veal, Vienna steak, chops or cutlets, beefsteak, fried sausage, brain, sweetbread, and fowl. Analyses of urine and faeces showed a diminution of chlorides and nitrogen indicating an abundant absorption of albumin. Microscopical examination of the faeces revealed an entirely normal condition. There were no putrefactive changes present, proving that the entire absence of the gastric juice, with its HCl, is without any influence on the extent to which putrefactive decomposition is developed in the intestine.

Ovarian Calculi.—Ries (*Annals of Gynecology and Pediatrics*, November, 1898; *International Medical Magazine*, January) reports observations made in three cases seen in one year. The fragments of two of the ovarian calculi were submitted to qualitative analysis and both were found to be composed of a mixture of organic and mineral compounds; the former consisted

chiefly of fibrous materials with minor quantities of fat and cholesterolin, while the mineral matter was made up of the carbonates and the phosphates of calcium and magnesium, with unimportant traces of chlorides and sulphates, presumably of sodium and potassium. The convolutions of the surface of the stones resembled exactly inside, as well as outside, those of the corpus luteum, and undoubtedly took their origin in simple corpora lutea.

Lymph-gland Juice in the Treatment of Cancer.—According to the *International Medical Magazine* for January, Snow (*Lancet*, October 15, 1898), basing his opinion on the fact that the malignant disease varies in its progressive infection of the lymph glands and seldom, if ever, invades those lying above the seat of disease on the lymph stream, advances the theory that these lymphatic glands act not only as filters but also in some way destroy the infecting cells which come to them in the lymph stream, and that the final involvement of the gland only occurs when the lymphatic gland has used up all its resisting power in the contest with the disease. He advocates the administration of a lymph-gland juice containing as nearly as possible the physiological elements of the glands in their natural state, hoping in this way to increase the nutrition of the glands and their power to overcome the infecting elements. He has already seen results which make him feel that the theory is not entirely without foundation and that it coincides with the general trend of modern scientific medication, which administers to the patient that natural element which antagonizes the disease but is not present in sufficient quantities in the particular individual attacked. He hopes, by advancing the theory, to arouse the interest of experimental physiologists who can carry on the research in this direction scientifically.

Born in an Elevated Sphere.—According to the *Chicago Medical Recorder* for January, Dr. E. A. Lightburne writes in the *Lancet* that he had been called a few days previously to attend a woman about to be confined on the top of a tramcar in Bow-road, London. On getting there he found the car on a siding and surrounded by a cordon of police to keep the crowd at a respectful distance. With the assistance of the police-matron and a bull's-eye lantern everything passed off very satisfactorily, the woman being safely delivered of an infant weighing eight pounds and a half.

Mud as a Health Food!—According to the *St. Louis Clinique* for January, it is a fact that a charlatan "professor" gave a lecture recently in Denver in which he delivered himself as follows:

"And now I am going to make known the greatest discovery ever made by mortal; every one hold fast to his chair and keep calm." A wave of expectancy swept over the vast audience and, amid a deathlike silence, the professor continued: "In my stupendous investigations of animal life I have discovered that dogs, horses, pigs, etc., were not troubled with dyspepsia, rheumatism, consumption, appendicitis, hysteria, and other ailments. I observed that all animals were very much given to eating dirt; this suggested the thought, Why not do like wise? and under the inspiration of the idea I commenced to eat dirt, and have been doing so ever since, with the result that my physical ailments have departed and I stand before you to-night the most healthy man in America. I guarantee, if any individual will take three doses of dirt a day, it will cure every disease that is

known to the medical profession. There is only one brand of dirt, however, that I can safely recommend, and it comes from the banks of the dear old Missouri River. Anticipating a large demand for it, I took the precaution of having a large consignment shipped to Denver. I have had this great Nature's remedy put up in neat boxes which will be sold at popular prices. Special rates will be made to large families and public institutions on keg and barrel lots. I will guarantee that it is the quintessence of the banks of the Missouri River."

The writer states that there were fools enough in the audience to enable the "professor" to exchange a large quantity of his Missouri realty for hard-earned dollars.

Abscesses of the Liver.—Dr. Edward E. Feild (*Georgia Journal of Medicine and Surgery*, December), in a paper read before the Virginia State Medical Society, said that among the predisposing causes of abscess might be mentioned:

1. Alcoholism.
2. Residence in tropical climates.
3. Any abnormal condition of the parenchyma caused by malaria, syphilis, new growths, cardiac insufficiency, renal insufficiency, hyperemia of liver, anemia of liver, tuberculosis.

It was reasonably certain, he said, that syphilis and tuberculosis did not directly act as exciting causes of abscess, but that the gummata of the former and the broken-down nodular masses of the latter offered a suitable nidus for the development of any of the pus-forming germs which might be present in the systemic or portal circulation.

While some authorities claimed that in abscess in infants tuberculosis was the exciting cause, the foregoing seemed the most rational explanation. It had also been pretty clearly demonstrated that malaria was only a predisposing cause, as the organism of Laveran seemed to cause a degeneration of the hepatic cells and had never been known, *per se*, to produce pus under any other circumstances.

Renal insufficiency from sclerosis, causing an imperfect depuration of the blood and a consequent increase of hepatic activity and hyperemia, and cardiac lesions inducing congestion, predisposed to abscess. The effects of alcohol were too well known to need further comment.

Residence in hot climates was undoubtedly the most frequent predisposing cause of hepatic abscess. Europeans resident in India were often attacked with abscess through disregard of the hygienic rules of the tropics, although the disease was also prevalent among the natives.

Men seemed to be more subject to the disease, owing to their greater exposure to alcohol and syphilis, the proportion being about thirty men to one woman.

Among the exciting causes of liver abscess should be mentioned in the order of their relative frequency: (1) Dysentery (mainly tropical dysentery), in which the *Amoeba coli* was generally present as a causative factor; (2) extension of inflammation from adjacent structures; (3) pyelophlebitis; (4) phlebitis of umbilical vein; (5) suppurating hydraditis; (6) actinomycosis; (7) trauma; (8) suppurating of gall bladder; (9) typhoid fever; (10) tuberculosis.

Tropical dysentery seemed by far the most frequent cause of liver abscess.

The author quoted Manson's figures as conclusive, as

to the existence of an intimate relationship between tropical dysentery and liver abscess. There was good reason, however, for believing that, while they represented the truth, they did not represent the whole truth, and that the association was even more frequent than they indicated. In a large proportion of cases of liver abscess the *Amaba coli* could be demonstrated.

The author then quoted a case to illustrate the connection between dysentery and abscess of the liver.

Symptoms.—Usually, when the patient came under observation, the symptoms of hepatic abscess were weight and fullness in the right hypochondrium; pain of variable intensity, but usually dull and aching, often referred to the right shoulder; tongue heavily coated; the bowels usually moved frequently, and the stools might or might not be acholic, as pressure from the abscess might affect the bile duct. There was usually insomnia. The temperature was variable, as in other cases of hectic, sometimes being subnormal and then suddenly rising to 104° or 105° F. The decubitus was right lateral or dorsal, usually with the knees drawn up. Palpation showed enlargement of the liver, often extending as low as the umbilicus. The enlargement was by no means symmetrical, but extended in whatever direction the abscess was located. There was often tenderness on pressure or percussion over the liver. The respiration was shallow and more frequent than normal. Rigors were not uncommon, and the patient often had night sweats. Rapid emaciation was the rule. The complexion was generally muddy and cachectic in appearance, but distinctly marked jaundice was rare. The spleen was rarely enlarged. A dry, hacking cough, evidently a reflex from irritation of the diaphragm or from an inflamed condition of lung or pleura over the seat of the abscess, was not unusual. Should the abscess discharge through the lung, the cough might be very severe and sometimes cause vomiting. It should be borne in mind that hepatic abscess often closely simulated malarial disease, and where there was a doubt of the diagnosis quinine should be withheld until the blood could be examined for the plasmodium. Manson thus emphasized the similarity of the symptoms of the two diseases:

"Perhaps the most common error was to regard the hectic of the liver abscess as attributable to malaria. The regularity with which the daily fever recurred, the daily chilliness or even rigor coming on about the same hour, the profuse sweating, and other circumstances so compatible with a diagnosis of malaria, all contributed to this mistake. So common was the error that Osler says he hardly ever meets with a case of liver abscess which has not been drenched with quinine. The author's experience was the same. He had seen medical men make this mistake not only in their patients but in their own persons. If carefully considered, there were several circumstances which should obviate so serious an error.

"1. No uncomplicated ague resists quinine in full doses.

"2. In malaria, if the liver is enlarged, the spleen is still more so; the reverse is the case in liver abscess.

"3. The plasmodium can not be found in the blood in nonmalarial hepatitis.

"4. In liver abscess the fever is almost invariably an evening one; in malaria it most frequently comes on earlier in the day.

"5. Quotidian periodicity, contrary to what is the case with tertian or quartan periodicity, is by no means pathognomonic of, nor peculiar to, malaria.

"6. The almost invariable history of antecedent dysentery, or at least of bowel complaint, in liver abscess."

Treatment.—When the diagnosis of abscess had been satisfactorily made, the author said the only rational treatment was to evacuate it as soon as practicable.

First, a point of fluctuation should be ascertained, if possible, or even a probable point of suppuration, and an aspirating needle introduced under strict aseptic precautions. A rather large needle should be used, as liver pus was generally very thick and would not pass through a fine needle. The needle should be pushed deeply into the liver and the piston pulled back, when, if pus did not flow, the needle should be slowly withdrawn in order that any pus which might have been traversed by the needle might drain into its lumen. Under no circumstances should the piston be pushed down during the removal of the needle, lest pus be forced into the peritoneum or pleura, but the vacuum should be maintained.

If no pus was found, the needle should be withdrawn until the point was near the walls, and, its direction being changed, it should be reintroduced as in the previous manner.

This procedure could be repeated several times without danger, with careful asepsis. It should be done under anesthesia, as it was quite painful, and if the pleura was punctured might give rise to unpleasant reflex symptoms. It was claimed by some writers that even if no pus was found this procedure would often relieve the existing symptoms.

Having located the abscess, the needle should be left *in situ* and a dissection carefully made down until the peritoneum was reached, if the incision was below the costal line, and if adhesions to the liver were satisfactory the liver should be opened and the abscess explored with the finger, due regard being had for the adhesions. If there were no adhesions and the case was not extremely urgent, the wound should be packed with iodoform gauze for forty-eight hours, or until adhesions were sufficiently strong to prevent infection of the peritoneum. If the case was urgent, the capsule of the liver should be sutured to the edges of the wound before opening the abscess.

If the abscess was covered by the ribs it would be necessary to resect about three inches of at least one rib, and, after stitching together the right leaflet of the diaphragm and the capsule of the liver, to open the abscess as in the preceding case. In either event the hemorrhage would be considerable, but could usually be pretty easily controlled by packing around the tube, which should be of glass, five eighths of an inch in diameter and fenestrated. After washing out the abscess with hot saline solution or sterilized water a heavy dressing should be put on and an abdominal binder applied. The after treatment should consist in irrigation and dressing the wound at least once a day. In order to cause the tube to drain properly it should be packed loosely with sterilized gauze for its capillary effect. Owing to contraction of the liver after evacuation of the abscess, the direction of the tube would often be so changed as to necessitate sometimes the use of a curved tube.

The bowels should be kept open. Tonics and a generous diet should be given to combat the large drain from suppuration. It was well to put the patient in a rolling chair as soon as possible after the operation and wheel him into the open air.

Every precaution should be used to prevent bedsores. The patient should recline on the right side as much as possible to facilitate drainage.

Tolerance of Two Bullets in the Brain.—M. Maurice Pollosson (*Lyon médical*, January 1st) recently presented to the Surgical Society of Lyons a patient who fired two bullets into his brain two months previously. Skiagraphy showed one of them to be situated within the frontal lobe of the brain, while the other rested on the orbital vault. There were no cerebral symptoms, but some ocular troubles—retraction of the visual field and dilatation of the pupil. Ophthalmoscopic examination showed anæmia of the papilla and dilatation of the veins. The condition of the vision tended toward improvement.

A Case of Generalized Epilepsy, with Death during an Attack; Yellow Softening and an Osteophyte found on Autopsy.—M. Devay (*Lyon médical*, January 1st) reported to the Society of the Medical Sciences of Lyons the case of a man, a painter and plasterer by trade, eighteen years of age, epileptic from his eighth year. The attacks, rare at first, had not interfered with his intellectual or physical development. He was about five feet four inches in height, and carried the head habitually bent forward. His physiognomy expressed some hebetude. He could read and write fluently without errors of orthography. His memory was good. M. Devay was present during several accesses, which were always of the same fashion. He always fell forward, and his face showed numerous traces of his falls, which took place without any cry, but with pallor of countenance. Convulsions, at first tonic, then clonic, appeared, and were always generalized. They were often accompanied by involuntary micturition and biting of the tongue. There was no aura. There were neither motor nor sensory troubles. The heart was normal, the genital organs well developed, and there was no lung trouble. The crises had reached the number of sixty-two in a month, though they fell later to twenty-three. He had been treated first with large doses of bromides (salt not specified) without improvement, and subsequently with oxide of zinc in daily amounts of from three to six grains, without effect. The drug was well tolerated. The substitution of powdered ipecacuanha in progressive doses, rising from one thirty-third of a grain to three grains daily, was equally without result. This treatment was continued up to the time of death without provoking nausea.

At the autopsy the thoracic and abdominal organs were found normal. The brain showed no adhesions save at a point in the left hemisphere at the union of the inferior parietal convolution with the first temporal. At this level there existed a depression the size of a fifty-centime piece, of the color of yellow ochre. On passing the finger over this focus of softening, after removing the cortex, the presence of a hard spot was determined. When caught with a forceps this hard body clung tenaciously to the brain substance, into which it seemed to send processes. The body was found to have the shape of an irregular pyramid. It was hard, glistening, and gave to the touch the sensation rather of bone than cartilage.

The author says that the autopsy presented the following points of interest: 1. From the view point of cerebral localizations the softening situated in the vicinity of the centres of verbal blindness and verbal deafness, and more especially at the level of the centres of movement of the upper eyelid, was not revealed in life by any clinical symptoms. It may be supposed that these were convulsive movements of the upper eyelid at

the beginning of the crisis, but the patient falling always on his face gave no opportunity of establishing this. 2. The existence of generalized epilepsy in association with a localized cortical lesion. 3. The existence in the zone of softening of a foreign body of osseous appearance and consistence, whose discovery was a veritable revelation of the autopsy.

The Gullibility of the Public.—According to the *Boston Medical and Surgical Journal* for January 19th, the *Practitioner*, in an interesting account of Sir William Jenner, in which his professional honesty and even bluntness is commented upon, gives the following excellent anecdote of another distinguished physician who had certain qualities which Jenner lacked. The story is taken from the *St. Bartholomew's Hospital Journal*: "Dining one evening in the company of some medical men, among whom was Dr. Martin, then physician to 'Bart's,' Sir William Gull declared that some amount of quackery was essential to success in medicine. 'It is an example of the old saying,' he averred, '*Populus vult decipi*.' The host asked for a terse English equivalent. 'Oh, that's easy enough,' said Dr. Martin quickly: 'The public like to be gulled!'"

Eruption due to Benzoate of Sodium.—M. Hébert (*Normandie médicale*, January 1st) describes a case of eruption due to the administration of benzoate of sodium. Upon the abdomen were large erythematous patches of irregular contour and in places confluent. Their color was a sombre red, and they became effaced under pressure. On the back and neck of the patient were some papule on an erythematous area. On the anterior and internal surface of the right lower limb, especially just above and below the knee, were large patches similar to those on the abdomen, but more livid in color. There was intense pruritus over the abdomen, and especially on the right thigh, causing severe scratching. The eruption disappeared on discontinuance of the drug. No antiprurine had been taken.

The Meharry Medical College.—The commencement exercises of the Meharry Medical College were held, according to the *Nashville American* for February 2d, at the Tabernacle in Nashville on February 1st. The medical department of the Central Tennessee College was established in 1876 as the first medical school opened in the Southern States for the education of colored physicians. At the commencement exercises Dr. Arthur J. Moore spoke on the Negro Physician as a Factor in the Solution of the Race Problem, and paid a high tribute to the white physicians for the friendly aid which they had extended to the negro physicians. William H. Lanester spoke on The Age of Pharmaceutical Progress, and Dr. J. C. Gaston delivered the medical valedictory, choosing as his subject The Qualified Physician a Necessity. He referred particularly to the possibilities of the physician in raising the standard of the mothers of a race, and made a strong appeal for personal individual culture along every line of thought and of the most thorough nature. Other speakers were Mayor Dudley and Dr. W. T. Rodgers. The Meharry Medical College owes its origin to the descendants of Alexander and Jane Meharry, who were of Scotch Irish descent and came to this country in 1794. Several Meharry graduates responded to President McKinley's call for volunteers in the recent war, and served in various capacities as surgeons, hospital corps men, etc. The course of study at

the McHarry Medical College is thoroughly graded and four sessions of five months each are required to complete it. The method of instruction differs from that which is followed by most medical colleges and is more like that pursued by literary schools. Daily recitations from text-books are required in anatomy, chemistry, and physiology during the first session; in anatomy, physiology, and materia medica during the second; while during the third and fourth, lectures and recitations are combined. Laboratory work in chemistry is required for three sessions.

Sir Joseph Fayrer.—*Janus* for January and February publishes a very interesting account, accompanied by an admirable portrait of Sir Joseph Fayrer, veteran surgeon-general of the British army. Sir Joseph was the son of Commander Fayrer of the royal navy and first entered the navy as an assistant surgeon, but subsequently resigned his commission in that service and entered the army. Sir Joseph Fayrer served in Lucknow through the siege during the Indian mutiny. His contributions to medical literature have been as varied as valuable.

Test for Iodoform Intoxication.—According to the *National Medical Review* for January, the following means (*Buffalo Medical and Surgical Journal; American Journal of Surgery and Gynecology*, 1898, xi, 119) may be resorted to for demonstrating in time a threatened iodoform intoxication, a condition which is not rare in surgical and gynecological practice: A test is made of the urine to note the quantity of iodine which is eliminated by it. A small pinch of powdered calomel is placed upon a white saucer, and then a few drops of the urine to be examined are dropped upon it; a mixture of urine and calomel is then made with a glass rod. If the urine contains a notable amount of iodine there is produced a well-marked yellow discoloration, which should indicate that the iodoform is being absorbed in sufficient quantity to produce danger.

The Treatment of Pott's Disease.—Dr. Galloway (*Canadian Journal of Medicine and Surgery*, February), in a paper entitled *Should the Deformity in Pott's Disease be Forcefully Corrected?* sums up his conclusions as follows:

"1. Sufficient experience with the operation of forcible reduction of the deformity in Pott's disease has been accumulated to enable each surgeon to decide whether the procedure is or is not at present justifiable. 2. The theoretical dangers of the operation have not received much support in practice, enough, however, to demand that they be taken into account. 3. Calot reports better results and appears to be more hopeful than any one else. 4. We should be justified in performing the operation if we could be sure of ultimate good recovery without deformity or with greatly diminished deformity. 5. Satisfactory evidence that the ultimate result will be good is wanting, while the *post-mortem* findings quoted are anything but reassuring. 6. Our knowledge of the behavior of tuberculous bone does not make us hopeful regarding the filling in of the gap created by the operation, and the admitted tendency of the deformity to relapse after correction increases doubt on this point. 7. Surgeons should cease performing the operation, and wait patiently until the ultimate results in a considerable number of the cases already treated have been determined; not condemning the operation in the meantime, but simply holding it *sub judice*. 8. As

an exception to the conclusion just stated, cases complicated by paralysis which can not be cured by other means should, in the absence of contraindications, be submitted to forcible reduction, as there is abundant evidence to show that the operation usually cures or improves the paralysis promptly. Very early cases with slight deformity may perhaps also be attempted. 9. The tendency to simplification of the original operation shows distrust for Calot's method, or points to its being unnecessarily radical. The method described by Goldthwait is simpler and more reasonable. 10. As a result of the world-wide discussion of this subject some advance in the treatment of Pott's disease may be anticipated."

Substitutes for Tuberculin in Diagnosis.—Dr. R. C. Cabot and Mr. J. J. Whoriskey (*Journal of the Boston Society of the Medical Sciences*, January 17th) have made experiments to test the comparative values of "artificial serum," somatose, and tuberculin as an aid to the diagnosis of tuberculosis. Check experiments were made in each case. The artificial serum was made according to the following formula: R Sodium chloride, 5 parts; sodium sulphate, 10 parts; distilled water, 1,000 parts. From fifteen to twenty cubic centimetres of this solution were injected subcutaneously with antiseptic precautions, and the course of the temperature watched for twenty-four hours. The somatose was used by injecting a cubic centimetre and a half of an aqueous solution of somatose. In some cases a one-in-one-hundred solution (representing a quarter of a grain of somatose), and in others a one-in-thirty solution (representing three quarters of a grain) was used. Twenty-one cases were tested with tuberculin. Dr. Cabot's conclusions are as follows:

"1. The tuberculin test in cases of doubtful tuberculosis can be safely and efficiently carried out under the conditions existing at the out-patient department of a hospital. 2. The substitution of sodium-chloride and sodium-sulphate solution proved, in my hands, a total failure. 3. The use of somatose, while somewhat more successful than that of salt solution, and while deserving of further study, has not shown that the regularity of its action is at all comparable to that of tuberculin."

Methods of Preserving Needles, with Recommendation of a New One.—At a recent meeting of the New York Surgical Society, Dr. Dawbarn (*Annals of Surgery*, February) recommended the use of a saturated solution of washing soda in water, for the purpose of preserving surgical needles. He stated that in his opinion this method of keeping the needles and cutting instruments untarnished was superior to any other which had thus far come within his experience. He showed needles kept bright in this way for a year and more. Most of the other methods are open to some objection. Perhaps the most common method is to sew the needles into an oiled cloth, but even this does not always prevent flecks of rust. As to keeping them in carbolized oil, this to some extent dulls the edge of the needles just as carbolic acid in watery solution does that of scalpels; lysol being a dark solution, the needles are not very easily seen in it; calcium chloride in a closed place to keep the air dry, with the needles lying on a dish near it, produces a curious tarnish, almost like rust; in Fuller's earth or other powders it is difficult to find the smaller needles; in alcohol, unless it is absolute (and absolute alcohol ceases to be absolute very soon), the

needles will finally rust. A solution of borax in water, as recommended by M. Maréchal, will also rust the needles as soon as the thin plating, which all needles have at first, becomes worn away from usage, exposing the steel beneath. Perhaps keeping needles in alcohol is almost as good a way as that under discussion; its only objection being the unpleasant oiliness. Calcium chloride in absolute alcohol—thus keeping it absolute—is effective, but comparatively expensive. The same is true of placing a sheet of gelatin in the absolute alcohol, the gelatin by its affinity for water keeping the alcohol absolute.

The method now advocated—washing soda dissolved in water to saturation—is without expense, and has been proved to be reliable.

More "Tips" for Practitioners: On the Diagnostic Value of Facial Expression.—Dr. F. E. Wiedemann (*Indiana Medical Journal*, January), in a paper read before the Vigo County Medical Society on this subject, generalized some often neglected information as follows: He said that to the casual observer the tuberculous, thickened, or flat nose meant nothing more than uncomeliness, but to Kaposi it meant intemperance, struma, or syphilis. Were we to be consulted for hemorrhoids in a woman presenting a red-tipped nose, we should be justly criticised by our wiser colleague if we did not give attention to the digestive tract.

Laycock placed great stress on the development of the external ear as significant of a corresponding development of the brain, the circulation and nutrition of which coincided to a similar state in the encephalic tissue. In what way the confluent ear and adherent lobule were often associated with cerebral deficiency he could not tell, but such was the case.

Any shrewd diagnostician could make the diagnosis of gout by observing that characteristic tense, red, and shining skin of the ear; or from the presence of small concretions beneath the skin of the helix; and there could be no doubt of a diagnosis on seeing the hæmatoma auris, or insane ear.

Much attention had been called to the diagnostic value afforded by the teeth, especially in regard to syphilis. He well remembered how much stress his professor of dermatology gave to the crescentic notch in the incisors, a condition almost absolutely diagnostic of inherited syphilis. Yet, he said, we must not confound the syphilitic teeth with the pitted or crazy teeth, as they signified one of the various cachexia, and had no relation to syphilis.

Although the eye had unlimited expression, yet its diagnostic value was great—so great that no one would offer the diagnosis of jaundice or profound anemia or uremic poisoning without first consulting the eye. He who once saw the prominent, staring eyeball would never need to be told that the case was one of exophthalmic goitre. The altered appearance of the eye in cataract, pterygium, or glaucoma needed no description. If we remembered the origin and distribution of the third, fourth, and sixth nerves, we could very often surmise a diagnosis. The two forms of areus senilis, the fatty and calcareous, were interesting, but must be carefully separated. The fatty form was usually associated with fatty degeneration of the heart, while the calcareous variety was consistent with excellent health.

In considering the innervation of the face, we might expect to find the evidence of anxiety and cerebral irritation in the upper facial zone, about the forehead and

eye, and the expression of bodily pain in the lower half around the nose and mouth. We should as readily expect to find the elevated upper lip and partial exposure of front teeth in a case of peritonitis as we expected to find abdominal tenderness.

The spasmodic "grim" risus sardonius, was almost diagnostic of tetanus, and what skilled accoucheur could not determine the welfare of his patient by closely observing her facial expression?

In diseases of children, facial expression was of the utmost importance, and was entitled to special study and consideration. A non-observing physician would never be skillful in treating infantile diseases. To that physician lividity induced by exertion and excitement, with normal respiration, meant little, but the observing physician had learned that it indicated malformation of the heart and vessels.

Temporary lividity sometimes occurred in acute diseases. What did the congested cheek of the child mean? We all expected to find in such conditions a febrile or an inflammatory disease, as surely as we looked for cerebral disease in transient circumscribed congestion of the face, ears, and forehead.

Other diagnostic signs in cerebral diseases were the oscillation of iris, inequality of pupils, and drooping of upper eyelids. Dilatation of the alae nasi during inspiration, with a contraction of the eyebrows and a countenance indicative of suffering, were associated with severe inflammation of the respiratory organs. Why did we anxiously ask the mother if the baby had tears during the act of crying? Because we had observed that the absence of tears meant a severe and probably a fatal prognosis.

In severe diarrhoeal troubles the rapid wasting of the features, causing deep suborbital depressions, prominence and pointiness of the cheek bones and chin, and hollowness of the cheek, were certainly too well known to need more than mention.

Hypertrophy of the brain was denoted by great expansion of the cranium above the ears, with but slight, if any, enlargement of the frontal portion.

If we were asked as to a prognosis in regard to an infant suffering from some cerebral or intestinal malady, we should have no hesitancy in pronouncing a most unfavorable prognosis were we to find a thick Meibomian secretion of a puriform appearance collecting between the eyelids.

Alteration of the face from facial paralysis, according to some writers, was of little account save for the ptotic effect; but when we stopped to think and remember the origin of the foramen of exit, the distribution and function of the cranial nerves, to his mind we need know little more for a correct diagnosis and prognosis. For example, in a case of facial paralysis the patient presented a striking condition. The right half of the face was expressionless; the wrinkles in the forehead were erased; the eye was abnormally wide open and possibly watery; the corner of the mouth drooped, and the patient was unable to completely close the eye, and complained only of tenderness and pain in the right ear; still, he was anxious to know if he would always remain paralyzed. What were we to do? First, ascertain the muscles involved; know the anatomy sufficiently well to give each muscle its respective nerve; then trace the nerve peripherocentrally through the substance of the parotid gland, the stylomastoid foramen, the aqueductus Falloppii, emerging through the meatus auditorius internus to its origin between the olivary and

restiform bodies. But long before we got to its origin we might discover in the region of the petrous portion of the temporal bone some trouble with the mastoid cell or some carious condition of the petrous bone. We should then have no difficulty in giving a prognosis.

Of course, in mild forms of facial paralysis, usually of a rheumatic type, the affection was usually referred to the facial muscles; but, as a rule, there was no difficulty in distinguishing between mild facial paralysis due to peripheral irritation and one of severe form where there was complete reaction of degeneration in the nerve and muscle. In connection with severe neuralgia, there might occur a contraction resulting in what has been called "histrionic spasm."

Dr. Ord's description of myxœdema was so full, and showed so clearly the importance of the study of physiognomy, that the author reproduced it *in extenso*:

The face, said Dr. Ord, was swollen in every feature, so as to suggest the existence of renal disease; the swollen skin was singularly waxy looking and anæmic, and the swelling affected dependent and non-dependent features equally. Thus the upper and lower lips were uniformly enlarged; the alæ nasi were thickened and broadened; the ridges of expression were blurred or coarsened, or the lines obliterated. The cheeks were overspread with a dull pink flush, abruptly limited toward the orbits, and standing in vivid contrast with the anæmic skin around. The face wore a fixed, heavy, and withal most sad expression.

If we would cultivate the faculty of observation more, Dr. Wiedemann said, we could sit in our office and read the diagnosis of almost all diseases on the physiognomy of our patients.

The Pathology of Acute Infective Amygdalitis.—Dr. Goodale (*Journal of the Boston Society of Medical Sciences*, January 17th), as a result of careful microscopical researches in the laboratory of the Massachusetts General Hospital, concludes that "acute amygdalitis due to infection by the *Streptococcus pyogenes* and the *Staphylococcus pyogenes albus* and *aureus* is characterized histologically by a diffuse inflammation of the parenchyma of the organ, appearing in the form of an increased proliferation of lymphoid cells and of the endothelioid cells of the reticulum, due probably to the absorption of a toxine formed in the crypts. While bacteria are rarely demonstrable in the tonsillar tissue in cases characterized by purely proliferative lesions, yet at times infection of the interior of the follicle occurs, giving rise to circumscribed suppuration and the formation of abscesses which eventually discharge into the crypts."

The Counter Attack of the Military on the Medical Service.—According to the *Lancet* for January 7th, "The *Derby Telegraph* for December 27, 1898, quotes a correspondent to the fact that 'there is a strong feeling throughout the medical profession in this country that the time is ripe for a new medical act.' We are quite certain that the law should be better able to deal than it is with offenders who are found guilty of posing as medical men, and the columns of the *Derby Telegraph* for January 2d supply us exactly with a case in point. It is the account of an inquest held at Derby. The deceased was a little three-year-old boy, and the day before his death a Captain Fielden had given his mother some ointment to rub on his head. The mother of the child said that she did not know whether Captain

Fielden was a qualified medical man, but the word 'dispensary' was on his window. Captain Fielden was next called and said that he was a retired captain of the Scots Fusiliers, that he amused himself by doctoring, and examined and prescribed for children and adults in the ordinary way only, making no charge. He added that he had been in hospitals and therefore felt competent to diagnosticate cases, that he 'would give certificates for death or burial if the coroner would let him,' and that 'qualified men were not allowed to use good remedies like he did,' as to do so was 'against medical etiquette.' The witness was then told by the coroner to write down the constituents of the ointment which had been rubbed on the head of the deceased just before death. Dr. W. Spettigue, of Derby, having informed the coroner of the real cause of the child's death, said that the ointment in his opinion had not accelerated the fatal termination, evidence which for the time being saved Captain Fielden from serious consequences. The coroner has, however, reported the facts to the proper authorities, and there ought to be some way of compelling the ex-officer of the Scots Fusiliers to cease from deceiving his poor ill-educated neighbors with his pretensions to medical skill."

We suppose that it was from "combatant" officers of this type that the strenuous opposition came to the now accomplished formation of the Royal Army Medical Corps. Was the gallant officer entering on a reprisal for fancied injuries?

Operative Measures for the Cure of Pruritus Vulvæ.

—Dr. E. C. Dudley (*Peoria Medical Journal*, January) says that when apparent causes have received due attention and the disease has resisted all other treatment operative interference may become necessary. Saenger's conclusions on this point are based upon experience, and deserve attention. He says: 1. The partial or total extirpation of the vulva is a legitimate operation that should often be performed in chronic, otherwise incurable, pruritus vulvæ, which he calls *vulvitis pruriginosa*. 2. The removal also of the glans clitoridis, especially in elderly women, is permissible. Its nerve terminations have usually lost their specific sensibility by reason of the disease. 3. In younger individuals, if the irritation is circumscribed, one may try to give relief by a partial operation without removal of the clitoris. 4. In elderly women, when the disorder is extensive, the whole vulva should be extirpated and the parts repaired by a corresponding plastic operation.

Poisoning by Bromoform.—Mueller (*Münchener medizinische Wochenschrift*, 1898, No. 38; *Giornale internazionale delle scienze mediche*, December 15, 1898) reports the case of a male child, aged two years, who was given ninety minims by mistake. Death ensued, with vomiting, convulsions, and asphyxia, after about four hours. The autopsy showed extensive blood dilution and marked injection of the cerebral and meningeal vessels. There are in all twelve cases published of bromoform poisoning. The stomach pump, artificial respiration, apomorphine, and injections of ether and camphor were the remedies tried. The author refers to the therapeutic results obtained with bromoform in the treatment of convulsive cough at the polyclinic of Monaco, where about a thousand cases were treated, and all with most favorable results. He recommends the admixture in order to avoid all danger of poisoning of a nuxia with alcohol and glycerin.

Original Communications.

A FEW INTERESTING PSYCHO-NEUROSES.*

By B. C. LOVELAND, M.D.

CASE I.—Mrs. G. L. came under my observation about the first of September; her age was about fifty-five; height, five feet six inches; weight, about one hundred and fifteen pounds; complexion sallow; gait rather stiff, and facial expression worried and anxious. She said her digestion was good, and that she slept fairly well, but complained habitually of extreme tenderness or painfulness in her hands and feet, especially in the plantar and palmar surfaces, this tenderness extending up the extremities toward the body.

On physical examination I could find no objective symptoms; her reflexes were normal; her sensations were also normal, including the sensations of heat and cold. The only thing noticed was the extreme tenderness of the extremities, sometimes described as a burning pain, sometimes as soreness. The position usually taken by the patient was one in which she would sit with her elbows resting on the arms of the chair, or on her sides, the hands supinated, her fingers separated in such

a manner that no finger touched the next. This position was maintained for hours, to prevent anything touching her fingers, for the touch of even a light paper seemed to give her pain or distress. Sometimes, in connection with the variations of tenderness, there was a flushing of the hands, in which they seemed to be slightly swollen or engorged with blood. This condition had existed for eight years, gradually increasing. It had been attributed to various digestive and uterine troubles. A few months previous to my seeing her she had had her ovar-

ies removed with the expectation of relief, but no relief was experienced.

Under my observation her general nutrition improved, but no material difference occurred in the feeling in her hands. After six weeks or two months the trouble was slightly better, but not sufficiently so to make any positive prognosis as to a radical cure. My opinion as to the cause of this condition was that it was an acro-paræsthesia, probably of hysterical origin, due to a prolonged nervous strain attendant upon family troubles. It had not been ascribed to this cause, but she had the constant care of a semi-insane relative, and I found that she was better when under my care, and would grow worse again at home, improving again when she went away.

A photograph, illustrating the position in which she held her hands, is here presented.

CASE II.—Miss L. F. was brought under my observation by a friend who was an old patient of mine, November 9, 1897. She was about sixteen years of age, the daughter of people in moderate circumstances. Her mother had suffered from two attacks of nervous prostration, and had frequent nervous chills and faint spells; her father was a healthy mechanic. The child had always been nervous and irritable, but her temper had entirely changed since her present trouble began, and she had grown docile and patient.

The statement I had of the case was that the girl had had hiccoughs daily and constantly for a year or more. The friend who brought her to me, a clergyman, told me, when she was shown to a room in the sanitarium, that he thought she would not be able to remain in the house and would have to take a room outside, because her attacks had been so noisy and protracted that they had disturbed the neighbors at home, and he did not think she could be kept in the sanitarium.

On first seeing the patient the opinion was formed, of course, tentatively, that the trouble was of hysterical origin, but no statement was made to the patient or to her mother until a careful examination had been made, when it was found that there was a habit chorea, as it might be called, affecting the diaphragm and abdominal muscles, an abdominal clonus, which was almost constant during waking hours, producing a sort of abdominal churning. This was present even when there was no hiccoughing, as it was called. The result of this somewhat strange diaphragmatic contraction was the ordinary churning motion which accompanied the hiccoughing, and which amounted, when an excessive spell occurred, to a barking almost as loud and violent as the barking of a dog; and it was these barking spells, rather than true hiccoughing, which had been the painful difficulty during the year and had annoyed the neighbors.

The treatment in the case was almost entirely moral; in other words, but little attention was given to the slightly sluggish liver, but a few baths and other treatments were given to occupy the patient's time and attention. It was stated that the condition was a purely hysterical one and subject to volitional control. The patient was instructed to control the first feeling of abdominal contraction and to divert herself every possible moment, and she was very strongly urged to this direction.

The second day she came to my office and reported that she had had five individual hiccoughs and no more; the third day, two or three; the fourth day, only one, and thereafter, until she left my observation about four weeks later, had no kind of hiccoughing.

* Written for the January meeting of Ontario County Medical Society.

A patient came to me recently from the same town who told me that she continued fairly well, but had occasional lapses, which I do not think is strange, considering that she has to live with her mother, whose nervous temperament was largely the cause of her trouble in the first place.

CASE III.—Mrs. F. W., a widow, about fifty-five years of age, whose husband had been dead about two months, came under my observation in January, 1897. She had suffered from nervous trouble more or less for four or five years; had had no children; had no organic trouble; no polypic trouble. She had been accustomed to use stimulants more or less to ward off what she thought were heart attacks, and when brought to me by her sister the object was largely to keep her from the habit of using stimulants.

The heart attacks of which she spoke were subjective entirely, and consisted of what she thought was a stopping of the heart's action, but, by observation of the pulse, we found that it did not differ much from the normal. The attacks were likely to come on almost any time, night or day, and when they did come on, they were ushered in by a feeling of choking in her throat, as if she were suffocating, and she would emit a sharp, quick, barking sound.

Simultaneously with the barking sound she would strike her chest with her left hand violently, pounding her chest, and this would be kept up so long and so loudly as to annoy the neighbors. This was the character of the attacks for which she had been accustomed to take stimulants, and the necessity for these stimulants arose very frequently. Hoffman's anodyne and valerianate of ammonia answered the purpose quite as well, but were not liked as well by the patient, so that soon after the change in remedies, and after a strong moral impression was made, the attacks subsided, and before she left they seemed to be quite subdued.

To try to explain these nervous phenomena in detail would involve an attempt to explain the psychology of the hysterical mind, which would be too deep and extensive a study for the present purpose. It is sufficient to say here that in these cases the trouble belonged entirely to the subjective realm, and when the idea was eliminated and others of a more useful character took its place the distressing symptoms subsided.

PAPILLOMA OF THE NASAL CAVITY:

A BRIEF REVIEW, WITH REPORT OF CASE.

By RICHMOND MCKINNEY, M. D.

MINNAPOLIS.

THE comparative rarity with which papillomata of the nasal cavity are found, in comparison with the occurrence of similar growth in other portions of the body, the larynx, for instance, renders them of sufficient interest to justify the reporting of every case encountered.

In reviewing the literature of the past fifteen or twenty years, one is struck by the apparent uncommonness of this condition. Indeed, when such an astute observer as Bosworth states (1) that in more than two hundred cases of benign tumors of the nose but one

of them was a papilloma, and an eminent English observer, Watson Williams, of Bristol, reports (2) having seen but two cases of nasal papillomata in his entire experience, we become more fully cognizant of the infrequency of the occurrence of this growth in the nasal cavity.

But while the majority of observers have been enabled to report only one or at most two cases of nasal papillomata, Hopmann (3) found in a total of four hundred and thirty cases of benign nasal tumors, seventy-eight of papilloma. At a later period Hopmann also states (4) that in one hundred and eighty-two cases of nasal polypus Schaeffer observed twenty instances of papillomata. This large percentage is somewhat offset by the report of Schmiegelow (5) who, in seventeen

FIG. 1.—Camera lucida drawing of a section of nasal papilloma.

cases of nasal tumors, found only one case of papilloma, while Zuckerkandl (6), in thirty-nine cases of polypi, also found but one case of papilloma.

Of the observations of Hopmann and Schaeffer, that excellent clinician, Bosworth, says (7) that he thinks it is not easy to harmonize them with ordinary clinical experience unless we recognize the fact that these growths are in the large majority of instances overlooked.

Further cases of nasal papillomata have been added to the literature of the subject by Mackenzie (8), Butlin (9), Aysguier (10), Verneuil (11), Cozzolino (12), Gamperz (13), Noquet (14), Baber (15), Wright (16), A. L. Turner (17). Bosworth (18) also calls attention to the fact that the case of follicular tumor of the nose reported by Ward (19), and the one called a condylomatous polyp of the nasal fossa, reported by Testelin (20), were in all probability instances of this disease. Douglass (21) has added the most recent case to those already reported. That in my search through rhinological literature I have overlooked reported cases there is every reason to believe, and that others have observed instances of the occurrence of nasal papillomata without reporting them, must, of course, be taken into consideration, but I have here made as complete records as circumstances would permit.

Hopmann differentiated nasal papillomata into two

varieties—the hard and soft—this classification being seemingly due to the character of the epithelial covering of the growth, those growths which appear near the margin of the nostril usually partaking of the hard variety, having a squamous epithelial covering, and only rarely attaining large size, while those which occur farther back and higher up in the nasal cavity, being covered with columnar epithelium, were said to be softer in consistence and to grow much larger. But the more recent investigations of Dr. Jonathan Wright (22) completely repudiated this classification of Hopmann, it being clearly shown by Wright that Hopmann had, as one of his varieties, described the ordinary polyp formation which had, from pressure, taken on a false papillomatous appearance. Dr. Wright's investigations have been confirmed by later observers, and only recently Dr. Benjamin Douglass, of New York, in reporting a case of papilloma of the nasal septum, cited above, clearly explains the difference in the microscopical structure of a papillary fibroma and a Hopmann polyp. We thus, then, as Dr. Wright states, are unable to say how many cases of true nasal papillomata have been observed. This later light upon the nature of the growths described by Hopmann would lead us, however, to infer that a large percentage of the cases of nasal papillomata reported by this writer as occurring in his own experience and that of others were not instances of true papilloma; thus emphasizing the rarity of the occurrence of these growths in the nasal cavity.

The general appearance of a nasal papilloma is that of a warty growth, being of a grayish pink or red color

FIG. 2.—Magnified sixty diameters.

and lobulated, the surface being irregular and coated to that of a raspberry. Nasal papillomata may also grow from the lower turbinal or septum and may be found ranging in size from that of a pea to that of a filbert, and may be either single or multiple.

In the treatment of these growths but one course is to be pursued—remove with the cold snare and cauterize the base with either the electric or chemic cautery.

My case is presented in a very few words:

W. B. M., aged twenty-four years, medical student, had noticed something which felt like a crust of mucus in the left naris on the upper and anterior portion of the septum for about six months. No discomfort was experienced other than some stenosis, which was not relieved by an attempt to clear the nose. He has had

FIG. 3.—Magnified three hundred and fifty diameters.

occasional slight hemorrhages from this naris. Examination revealed a growth about the size of a coffee bean attached to the upper and anterior portion of the cartilaginous septum behind the tubercle. The growth had a warty, mammillated, raspberry-like appearance, and was of a pale pinkish color. From its consistence and general characteristics I was led to believe it to be a true papilloma. After examining it, I removed it with the cold snare and cauterized the base with the electrocautery. Six months later this growth had not returned.

The accompanying photomicrographs show conclusively that mine is a case of true papillary fibroma, but in further testimony thereof, through the courtesy of Dr. William Keen, a pathologist at the city of Dr. Jonathan Wright, of Brooklyn, and Dr. Benjamin Douglass, of New York, I am enabled to append the following reports as to the microscopical character of the growth.

The histological examination of the growth you sent me shows it to be a fibrous papilloma. Please find the full specimen.

Yours very truly,
[Copy] Wm. Keen, M.D.

Your favor of Feb. 21st, with the growth attached, I should think the growth from which you sent me to be a fibroma papillare or true papilloma.

Thanking you for bringing this case before my attention, I remain,
[Copy] Very truly yours,
Jesse Max Weinert

The specimen you sent for examination is clearly a true "papillary fibroma" or papilloma and not a Hop-

mann polyp. It presents all the necessary qualifications to class under the genuine head. May I thank you for sending it to me for examination? Sincerely,

[Copy.] BEAMAN DOUGLASS.

CONTINENTAL BUILDING.

THE WEIGHT IN THE FIRST TWO YEARS OF LIFE, WITH A DESCRIPTION OF A NEW WEIGHT CHART.*

By J. P. CROZER GRIFFITH, M.D.,

CLINICAL PROFESSOR OF THE DISEASES OF CHILDREN IN THE
UNIVERSITY OF PENNSYLVANIA.

THE importance of accuracy of standards in all branches of science is well illustrated in its application to the normal weights and rates of increase of weight of infants at different ages. Yet the difficulties encountered in determining standards in this connection can be realized after a glance at the considerable number of tables and weight curves which have been constructed and at the variation which exists among them. As a matter of fact, from the very nature of things, there can be no hard-and-fast rule according to which children must grow. The normal variation in weight of different newborn infants necessitates either a persistent difference in the weight line as time passes, or a greater rate of increase in those who start behind in order that the lines may finally become one. There are, besides, many difficulties attending the calculation of the normal weight of any infant. For instance, the weight im-

mediately after feeding is, of course, greater than that just before. Then, too, weight is sure to vary, depending upon the amount of food taken, the emptying of the bladder and bowels, the amount of exercise or of perspiration, and even on the ordinary metabolic changes going on during sleep. Thus, it has been found that the infant's weight on being put to bed at night is distinctly greater than when it is taken up in the morning.

Yet, in spite of these elements of uncertainty, it is necessary to possess at least an approximate standard with which any infant's weight can be compared, and by which its gain or lack of gain can be measured. Raudnitz* has even gone so far as to formulate an algebraic equation, by means of which the proper weight of an infant of a given age can be calculated—a law of weight analogous to that formulated by Liharzik for length, and, like it, of no great practical value.

Indeed, the formulating of any such rule for practical application seems impossible. The best that can be done is to determine by a larger number of weighings a general average which may be conveniently tabulated or represented graphically in the form of a weight curve.

There are two methods by which such average weights have been sought, called, respectively, the generalizing and the individualizing. In the former a large number of children of the same age are weighed, and the mean weight is calculated. Another large and, probably, different number of children of another age are likewise weighed and the mean weight of these taken; and so on for the different weeks or months of the period of infancy. This is by far the most convenient and sometimes the only practical method. The objection to it emphasized by writers, and very evident, is that its results may be most misleading. For instance, it is easily conceivable that the children of, say, four months of age may happen to be especially well developed. It might thus occur that the average weight of four-months' children, might even seem to be greater than that of children of four months and a half. Of course, the larger the number of apparently healthy children weighed the less the chance of error becomes, but the number must be very large to reduce the possibility to insignificance, and for the results to become serviceable.

How deceptive the generalizing method may be is well shown by the observations of Lorey.† This writer made weighings of five hundred and sixty-five children, two hundred and eighty-six of which were boys and two hundred and seventy-nine girls. In spite of this large number, it is quite evident that the irregularities which his weight curves show (Chart I), especially in the second year, do not represent the actual condition to be expected in the average child. In the combined curve for both sexes for the second year, as deduced from his figures and shown in Chart II, it will be noticed that

* *Prag. med. Wochenschr.*, 1842, Nos. 7 and 8; Cramer, 251.

† *Jahrbuch f. Kinderheilk.*, 1888, xxxii, 339.

* Read before the Philadelphia Pediatric Society.

children at twenty-one months weigh less than they do at twenty months, and again less at twenty-four than they do at twenty-three months. This certainly does not represent the true state of the case. Lorey makes no claim that his figures yield any statistical results, although based on so many cases.

CHART I.

For the most exact study of the rates of growth the individualizing method is better, and is the one that has oftenest been selected by recent writers. This consists in the keeping of a record of the weighings of an individual child, made at regular, frequent intervals throughout its life as an infant, and in the comparing this with a large number of similar records of individual cases. In this way the mean weights, and especially the mean rates of increase for different periods, can be readily computed, and better results obtained with a very much smaller number of cases.

It has been of interest to me to compare the various tabulated observations which have been made, in an effort to determine in this way the weight curve which best represents the growth of the child during the first two years of life. Perhaps the oldest and one of the most quoted tables of growth is that of Quetelet, which is more ideal than actual, and, as plotted by Bouchaud,* gives a straight line rather than the curve which represents the actual condition of affairs. Lorey has

stood (see Chart II). The straight line results from the assumption that the rate of growth is the same for all periods of the first year.

A second much-quoted estimation is that of Bouchaud.* Although his observations were made by the individualizing method, Bouchaud has rounded off his figures to such an extent that his final table of growth is much too schematic. The plotted curve is, however (Chart II), a more accurate representation than that of Quetelet, although it gives a rate of growth lower than may be expected of the average healthy breast-fed infant.

A table of weight constructed by Fleischmann† by the individualizing method applied to fifteen breast-fed children is often referred to. I have plotted the curve derived from these figures in Chart II. It shows well the rapidity of growth of the first months, and the diminishing rate during the succeeding months.

Recently a useful curve has been published by Holt,‡ constructed apparently by the individualizing plan (Chart II).

One of the most careful studies of the subject is that of Camerer.§ This observer has followed by the individualizing method the rate of growth of a large num-

CHART II.

ber of children during the first year of life, and compares the similar observations of Fleischmann, Lorey, and others, and has plotted the curve which, on the whole, most nearly represents the actual condition of affairs. Attention is called to the fact that the initial weight and age of the children are not the same, and that the curves represent the average weights, and are not the actual weights of any one child. The curves are based on human milk or cow's milk, and are not intended to represent the growth of children who have been fed on other food.

* *Revue de Pédiatrie*, 1897, p. 100.
 † *Archiv für Kinderheilkunde*, 1897, p. 100.
 ‡ *Archiv für Kinderheilkunde*, 1897, p. 100.
 § *Archiv für Kinderheilkunde*, 1897, p. 100.

being taken as types—for which, indeed, they are not intended. In Chart II I have plotted the curve of his figures for breast-fed children with an initial weight of over twenty-seven hundred and fifty grammes (six pounds one ounce). Camerer also gives some estimations of the rate of growth during the second year (see Chart III). Another observation upon growth in the second year is that of Lorey, already referred to. In Chart II I have combined his curves for boys and girls respectively during the second year, thus eliminating some of the irregularities.

In all the curves represented in Chart II all figures originally in the metric system have been reduced to avoirdupois weight, for convenience of comparison.

I wish to exhibit a weight chart which I have constructed (Chart V) in the effort to represent as nearly as possible the average rate of growth of healthy breast-fed children. Although to a certain extent schematic, as any averaging chart of this nature must necessarily be, it is, I think, as accurate as can be expected of any one suitable for practical purposes. It has been made after a careful study of most of the available published data, although it follows Camerer's curve more nearly than any other. The fact that it is so often necessary to record the weight of poorly developed children during the second year necessitated the representing in this chart of the continuous growth for the first two years of life. The line passing obliquely through it represents, of course, the rate of growth of healthy breast-fed children. Bottle-fed babies, as a class, fall below this

tal line represents a difference of four ounces. A gain of two ounces or even less can be indicated by marking between the lines. The weight should be taken weekly and recorded by dots connected by a line, as in a tem-

CHART IV.—Weight in the first ten days.

perature chart. For convenience, the figures at the top show not only the weeks but the months as well. In order to prevent the chart from becoming of an unmanageable size the portion for the second year—since this will be needed less frequently—has been narrowed in such a way that the space for four weeks is of the same breadth as that for two weeks during the first year. This necessarily distorts the proper position of the plotted curve, and gives the erroneous impression to the eye that the child grows as rapidly during the second year as during the first. It is evident that if the spaces for the years were of equal breadth the curve in the second year would be very much nearer a horizontal line. For practical purposes this distortion of the curve is of no moment, since its actual relation to the figures is unaltered. These charts in blocks of twenty-five may be obtained from the publisher, Mr. W. B. Saunders, of Philadelphia.

weight, still no mean necessarily so. There is also found a difference in weight depending upon sex, boys being heavier than girls. This difference may, however, be ignored in the connection. Each horizon-

There are a few matters remaining to which brief reference must still be made: First, the birth weight assumed, seven pounds and three quarters, is somewhat

INFANT'S WEIGHT CHART.

Illustrated by J. P. Crozer Griffith, M. D.,
Clinical Professor of Diseases of Children in
the University of Pennsylvania.

CHART A

more than that given by many writers. Yet it agrees practically with the statistics of Fleischmann, as also with those of Camerer for many of his cases. Should a child at birth weigh much less than this it is to be expected that the rate of growth will be very much the same. This will give a curve slightly below that of the chart. But a child which weighs over seven pounds at birth may be expected to reach the full normal weight by the age of one year.

Then, as to the loss of weight which the child suffers after birth before its regular gain begins. Although this does not necessarily take place, yet its occurrence is the rule and may be considered physiological. This was shown by the interesting experiments of Ingersley,* who allowed sixteen children immediately after birth to be suckled regularly by women who had been confined a few days before. The remarkable fact was noticed that the children showed not only a greater but a more prolonged loss of weight than the average.

There have been various estimations made of the degree and duration of loss. Some of these I have depicted in Chart IV, including the observations of Gregory,† Kezmar-ky,‡ Holt,§ Comby,|| and Haake.^A In all cases statistics in the metric system, or, as in the case of Haake, in the old German system of weights, have been changed into pounds and ounces avoirdupois. The curves of Gregory and Kezmar-ky, it will be noticed, run much together. The first was based upon observations made on thirty-three and the second on thirty-two healthy, breast-fed children. Kezmar-ky explains the greater duration of loss in his cases and the slower gain, as compared with Gregory's, on the ground that the children under his care were not nursed with the regularity which was desirable. In Gregory's they have nearly regained the normal weight by the seventh day; Kezmar-ky's fall much short of this. These two curves are largely in accord with the observations of Winckel,¶ and seem to represent the experience of most investigators. The curve representing the table of Comby seems to be largely schematic. I can not find on what actual observations it is based. The curve of Holt represents his experience with a hundred healthy, breast-fed children. It differs from the others in the greater degree of loss of weight, which equals ten ounces (two hundred and eighty-four grammes). This, however, is in accord with the observations of Townsend‡ on the records of two hundred and thirty-one breast-fed children in the Boston Lying-in Hospital. Here the average loss was two hundred and

seventy-nine grammes (9.8 ounces). I presume, however, that children suffering from illnesses were not excluded in making the computation. The observations of Haake on a hundred healthy, breast-fed children, as shown in the curve, not only give a loss which is less than that usually accepted as the common one, being but a hundred and sixty-three grammes (5.75 ounces), but also an initial weight lower than the average.

According to Fleischmann, who has made a careful study of various writers' estimations, the average total loss equals two hundred and twenty-two grammes (7.8 ounces). The duration of loss is two or three days, and sometimes longer. The total loss equals about one fourteenth or one fifteenth of the initial body weight. Increase in weight begins on the second to the fourth day, but the original weight is seldom regained before the eighth or ninth day or even not before the tenth day. The chart I have designed (Chart V) shows the approximate loss existing at the end of the first week, but not the greater loss which had taken place before this date.

Lastly, the variation in the weight curve of any infant which a weight chart will show, must be borne in mind. Not only will there be a variation dependent upon the fullness of the stomach, bladder, and bowels, as already stated, but there is a variation which does not rest upon these factors and yet which can not be called pathological. For instance, it not infrequently happens that a baby goes, it may be, a week without a gain in weight, or even shows a loss, and yet can not be called ill. Yet such a condition always, of course, should arouse watchfulness.

The value of the systematic recording of an infant's weight scarcely needs to be emphasized. Every physician especially interested in diseases of children fully recognizes it, for he knows that often a failure to gain, even before the child shows to the eye any ailment whatever, may be the sign that some form of illness is present or that the child is underfed. The weight chart is even more valuable than the temperature chart in the case of infants. The weighing, too, is such a simple matter that there is no excuse for a failure to have it carried out by the mother, at least once a week, and where a change in the method of feeding is being made, twice a week. Good spring scales showing ounces are not expensive, or a steady and ordinary kitchen scales with weights will answer. But best are some of the standing spring scales fitted with an oblong basket or a scoop, and which shall be devoted solely to the weighing of the baby. In my office are small platform scales with a specially large scoop which weigh from half an ounce to fifty pounds, and which I find indispensable.

It is, of course, understood that the weight recorded is that of the child undressed. If undressing at every weighing is inconvenient, the child may be weighed when dressed and then when undressed, and the weight of the clothes deducted. At subsequent weighings, then,

it is only necessary to see that the clothing is exactly similar, and undressing will not be required.

EMPYEMA:

INCISION AND DRAINAGE SUCCESSFUL IN TWO CASES OF
VERY LONG STANDING,
WITH PERFORATION OF THE LUNG AND OF THE
THORACIC WALL.

By SINCLAIR TOUSEY, A. M., M. D.,

ASSISTANT SURGEON, ROOSEVELT HOSPITAL, OUT-PATIENT DEPARTMENT;
SURGEON IN CHIEF, ST. BARTHOLOMEW'S CLINIC.

In each of these cases, cited from private practice, the amount of fluid was large, the lung had been compressed for a long period of time, and under expectant treatment perforation of the lung and of the thoracic wall, with the formation of a subcutaneous abscess, had taken place before the services of a surgeon were sought. They will be seen to have been severe cases and to have been successfully treated by simple incision and drainage, but they are not offered as an argument against resection of the ribs in the operative treatment of empyema. The author employs both operations, and offers these two cases for consideration in making choice of the operation to be performed:

The first patient, J. C., a boy of fourteen, was a delicate little fellow with kyphosis in the dorsal region. Following the *grippe* he had had pain in the left side of the chest for four months before I was called in to take charge of the case. Finally, a large subcutaneous abscess had appeared at about the level of the ninth rib, with the point of greatest redness and fluctuation in the ninth left intercostal space about three inches from the line of the spinous processes. He had had chills and fever of a remittent type.

On examination I found flatness over nearly the entire left side of the chest, and a fluctuating swelling in the situation already described. The diagnosis was empyema with perforation of the thoracic wall. Drainage was imperatively demanded, but the decision as to resection of one or more of the ribs was left to be made at the time of operation.

Under ether and with full antiseptic precautions a straight incision was made in the ninth left intercostal space over the area of greatest swelling and fluctuation. A pint or two of creamy pus was evacuated and the finger was introduced to explore the cavity. This was found to be the pleural cavity, and the lung to be considerably compressed. The intercostal space was wide enough to admit of the introduction of a large rubber drainage tube four inches long, and no resection was done. The cavity was not irrigated at the time of operation, and an absorbent antiseptic dressing was applied.

The discharge was very abundant for a time. For the operation, and the cavity was irrigated with Thiersch's borosaccharine solution every other day for three weeks. At the end of this time the lung had considerably expanded, and the cavity into which the tube sinus led had become very small. The tube was shortened so as to just pass through the thickness of the chest wall, but the discharge continued at the rate of a tablespoonful a day for six months. There then remained little more than a tube sinus, and the was

injected with a ten-per-cent. solution of permanganate of potassium. There was an immediate fit of coughing, with expectoration of mucus deeply stained with the permanganate. The same symptoms followed the injection for a few times and then ceased. The tube was now left out, and the sinus was injected twice a week with the same solution. It finally closed about six months after the operation. At intervals of several months for the next year the sinus would reopen and discharge a drop or two of serum. No diseased bone could be felt, and the pleural cavity never refilled. The discharge then came to an end, and the side has now been perfectly healed for several years.

The second patient, S. A., a boy of nine, had pneumonia during January, 1897. He made a good recovery, but had a relapse after going out of doors. Recovery from this was slow, and finally was interrupted by the appearance of unmistakable symptoms of empyema.

The family reside in a little village in New York State, and their physician called in a consultant from the nearest city. They decided to employ expectant treatment, poultices and measures for sustaining the strength of the patient. After the empyema had been present for about three months, an abscess pointed in the fourth left intercostal space an inch to the right of the nipple line. A half-inch incision was made through the skin and a rubber tube introduced into this superficial cavity. The tube slipped out on the following day and was not replaced.

When I first saw the boy on July 24, 1897, pus was still oozing from this puncture, and yards of sheeting were used every day in absorbent pads. There was flatness over the entire left side of the chest; voice and breathing were absent there, and the apex beat could be felt close to the median line. There had been for four months an evening temperature of 102.5° F., and there was constant and profuse purulent expectoration. Several yards of muslin were used every day as little handkerchiefs for the expectoration, and were burned after use. As was to be expected, there was an extreme degree of emaciation and an almost waxy transparency to the flesh. Besides the puncture from which pus was oozing, another abscess, with gaseous crepitus, was forming in the second left intercostal space in about the same vertical line. My diagnosis was a large accumulation of pus in the left pleural cavity, forcing only an overflow, not drainage, through the sinuous opening present. I arrived there in the evening, and, after making an examination, was driven miles through the country to see the family physician, who had not been told just when I would come up from New York. It was raining and absolutely dark, but we finally got to the doctor's house and called him up. We found that he had been waiting for me as to the necessity of operative interference, and he promised to assist me on the following day.

The boy's condition being altogether too weak to allow of the use of a general anesthetic, the following plan of Maendel's solution of nitrochloroform was adopted. Hypodermically, the skin was chloroformed, ether, and local anesthetic was produced by rubbing with ethyl chloride. An incision was made in the fourth intercostal space near the median line, and, after about three parts of empyema were evacuated, the finger introduced into the pleural cavity, and the incision was made to be near the bottom of the cavity, and the lung to be out of reach, so much as to be out of the way. Two good sized fenestrated rubber tubes were inserted, which had been made self-sealing by sitting in the

internal ends and spreading them out by a stitch or two taken in the rubber. An absorbent antiseptic dressing was applied, no irrigation having been employed.

After the operation the temperature varied between 98° and 99° F.; cough and expectoration ceased at once and entirely. There was a rapid gain in weight and strength. On September 13th the patient weighed sixty-one pounds, only seven pounds below his weight before this illness; the apex beat was in the normal site, and the left lung was being used to some extent. The tubes were left in place and nitrate of silver applied to the exuberant granulations about the orifice. On October 2d one tube was left out and the other about a month later. In this case the pleural cavity had never been irrigated at all. The tube sinus was now syringed daily with a ten-per-cent. solution of permanganate of potassium; it closed completely and permanently about December 1st. Since that time he has been in splendid health, and now no perceptible difference exists between the two sides of the chest.

In each of these cases surgery had not been resorted to until there had been perforation of the chest wall with pointing underneath the skin, and there were also unmistakable evidences of perforation of the lung. In the one case this was shown by profuse purulent expectoration, which ceased absolutely the moment drainage was established, and also by gaseous crepitus. In the other case permanganate of potassium appeared in large amount in the sputum when the tube sinus was injected with that drug. They were both cases where effective drainage could be secured without resection, and both made complete recoveries in an average length of time.

151 WEST SEVENTY-SIXTH STREET.

ON MORPHINISM.

By LOUISE G. ROBINOVITCH, B. L., B. S., M. D.

PARIS.

LATE RESIDENT PHYSICIAN, BLOCKLEY HOSPITAL, PHILADELPHIA;
LATE ASSISTANT PHYSICIAN, NEW YORK CITY ASYLUM FOR THE INSANE, ETC.

MEDICAL literature is replete with treatises on the remedial management of morphinism and the allied ailments; yet their origin, their pathology, should be deemed quite as worthy of investigation.

Is a subject addicted to the morphine habit in possession of the normal mental equilibrium, and, if not, how does this equilibrium differ from the normal?

In the large class of hereditary degenerates the clinician is confronted with a most astonishing variety of mental manifestations. They perform acts of which they are either ashamed, or which they subsequently deplore; and yet, in both cases, they find it impossible to govern or re-train their inclinations.

"*C'est plus fort que moi*" is an expression which gives the correct description of such patients' condition under these circumstances. They struggle against their inborn desires with all the strength of will they possess, but generally fail to conquer their inclinations.

I have a patient under observation who, coming

from a highly nervous and insane family, suffers from a most peculiar impulse, which prompts him to grasp any inanimate object and to squeeze it until he exhausts himself; he then loosens his grip. He is subject to a series of other as remarkable obsessions and impulses, but this one developed to such a degree that he became incapacitated for his work and had himself committed to the Sainte-Anne Asylum. He has an appetite, so to speak, for catching hold of objects and squeezing them. He is perfectly lucid; understands that he must not give way to his impulse; but when under its influence his will power is reduced to the point of non-existence. At first, this impulse came only at rare intervals, but in 1897 it had become almost constant; no sooner did he loosen his hold upon one object than he would grasp some other, such as a chair, a table, a projection of the wall, a door knob, his mother's skirts, a penholder, etc.

Another patient under my observation at the Sainte-Anne Asylum is subject to an impulse which prompts her to kill her two younger children, the eldest one having absolutely no influence upon her. Yet she actually loves all three of them equally; she mourns her fate; she would do anything in her power to rid herself of that impulse, as she is a most devoted mother and wife. She, too, is perfectly lucid mentally, having neither delusions, hallucinations, illusions, nor delusional interpretations.

Such patients, belonging to the class of hereditary degenerates, are not different, as a class, from the morphinomaniacs. The latter class, as it is understood by M. Magnan, is rather rare. The morphinomaniac is a patient who eats morphine by force of impulse, just as both of the above-cited cases perform their acts through the influence of irresistible impulse. The morphinomaniac is like the dipsomaniac, who drinks alcohol because of the promptings of impulse, although he tries his best to resist it. A dipsomaniac in M. Magnan's service at the Sainte-Anne was so grieved because of her affliction that she put fecal matter into the alcohol so that the consequent disgust might prevent her consuming the draught, but even this heroic measure failed completely. When the impulse came, she swallowed the mixture and satisfied her craving.

The morphine eater differs from the morphinomaniac just as the chronic alcoholic differs from the dipsomaniac. Both the morphinomaniac and the dipsomaniac absorb their respective drugs by impulse, while the chronic alcoholic and the morphine eater indulge their craving because of lack of resistive will power, the difference between the two lying entirely in the form. Clinically, however, both belong to the class of mental degenerates.

We are not prepared to localize the cerebral lesion which causes the disease, as one could localize it in a right or left hemiplegia, but the lesion exists, nevertheless. Whether the appetite is too exaggerated, the will too weakened, or whether there is simply a general

solution of continuity in the connecting fibres which, by their communicating agency, maintain the psychic harmony, there certainly is a material cerebral defect.

Morphinomania or morphine eater, the subject generally presents quite a clinical tableau, indicative of mental degeneracy, of which the most prominent feature is only one symptom.

The following case serves to sustain this position regarding the status of the morphine eater:

Mlle. Anite C., modiste, thirty-four years old, entered the Sainte-Anne on the 12th of April, 1897.

She is a natural child. Her father died of an apoplectic attack; her mother had numerous nervous spells; she was irritable and unruly, and inflicted bodily punishment upon her children to an unusual extent; she also drank to excess. She was the mother of nineteen children, the greater number of whom died during infancy, or were stillborn. Five children are now living, of whom, besides the patient, there is one sister who is extremely nervous, irritable, and who, like the patient, also has the morphine habit.

From the age of twelve the patient has been of a melancholy turn of mind, and once, while under the unkind treatment of her mother, she attempted to commit suicide by swallowing an infusion made from matches. At the age of thirteen she had typhoid fever in a severe form. At fifteen she, for the first time, had an attack of hysteria, which was preceded by an aura with hallucinations. Flames flashed before her eyes, and then came a convulsive attack; but she did not bite her tongue and there was no foaming at the mouth. These attacks lasted from ten to fifteen minutes. At the age of sixteen she fell in love with a man with whom she lived nineteen months. At the end of this time she found it uninteresting to continue her relations with him and began practising abortions on herself, which soon caused a metrapéritonitis. As a result of this it soon became necessary for her to enter a private sanitarium for treatment. She secured admission to the Dubois Hospital, where she for the first time received hypodermic injections of morphine, and soon became addicted to the drug. Her physician vainly endeavored to suppress the injections; she bought some morphine herself clandestinely, and after her discharge from the sanitarium in 1881 she used twenty centigrammes of morphine, in ten injections, daily.

She came home incompletely cured, still suffering from pelvic pains, to allay which she soon began to take thirty centigrammes of morphine a day. This continued for one year. Naturally, as a result of this system of life, she lost her appetite, slept badly, and suffered almost continually from oppressive nightmares. The malaise in the mornings was relieved by fresh injections of the drug. Menstruation stopped completely, and she soon found herself an absolute slave to the medication. She was forced to gradually increase the dose, until she was giving herself from ten to twenty consecutive injections at one time. She made such concentrated efforts that she had to keep them warm in order to prevent crystallization of the morphine salt. The constant puncturing of the skin soon brought on trophic and alcoholic lesions, for the treatment of which she entered the Necker Hospital in 1887. She left there, however, after a short stay, as she could not endure the progressive diminution of the morphine doses. In 1888 she was treated at various hospitals, notably at the Charité and

the Beaujon. The sudden suppression of the drug in the latter hospital caused overpowering vertigo, vomiting, and syncope. Not possessing sufficient courage to undergo this strict régime, she soon obtained her discharge. In 1885 we again find her, however, entering the Charité. At that time she presented marked amblyopia of the left eye and suffered from a premature falling out of her teeth. After a lapse of a month she obtained her discharge without having improved to any appreciable extent. She was then taking four grammes of morphine in thirty grammes of water, by the mouth. As this had no pleasant effect upon her, causing her, on the contrary, to suffer from headaches and extreme excitement, she again had recourse to the hypodermic injection, taking two grammes and a half of morphine a day. This abuse was followed by a profound cachexia, which forced her again to enter a hospital, the Hôtel-Dieu this time. There she again deceived her physicians, secretly giving herself injections, and upon being discovered was sent away. As her condition was precarious, she committed herself to the Sainte-Anne Asylum on the 16th of February, 1886.

She was very emaciated, weighed only forty-four kilogrammes, and presented hysterical spots and anæsthesia. There was complete loss of appetite, obstinate constipation, a bleeding gingivitis, and looseness of the teeth, due to a general alveolar periostitis. Sleep was absolutely impossible.

The method of gradual diminution was employed, and the patient apparently stood it very well, until it was learned the she received morphine carefully packed in spoils of silk, or in the candy which was brought her from outside.

The morphine was then suspended abruptly on March 25th; she became much excited, had incredible vomiting, diarrhoea, and alarming symptoms of collapse. A few days later, however, she began to feel better, her appetite returned, and she even increased in weight. This improvement became so marked that menstruation, which had ceased entirely during the previous six years, reappeared.

The patient left the asylum on the 1st of June, 1886, in good condition, the amblyopia having completely disappeared. But on her return home she found herself near her sister, who was also suffering from morphinism. The patient, under the influence of the surroundings, again picked up her morphine habit, taking injections of two grammes a day.

In 1887 she was treated at the Salpêtrière. In 1888 she entered Laenec, where she administered to herself clandestine injections and, upon this being discovered, was summarily discharged. On the 9th of January, 1888, she entered the Sainte Anne.

She presented then hallucinations of a most terrifying nature; she was persecuted by ferocious blood animals, etc.; she slept badly, had numerous nervous spells, and exhibited suicidal tendencies. These were caused by her despair of recovery from her long time habit. Her memory was much impaired, and she was in reference to recent events. Her general condition, however, fearful, her genital pharynx was much inflamed, and her heart was in a state of exhaustion; but it was necessary to suppress the morphine gradually. She was given coffee and spirituous drinks, and was enabled to enable her to sleep. From the 1st of March to the 15th of January she exhibited alarming symptoms of morphinism, namely, vomiting and epistaxis, etc. On the 15th, however, she had completely recovered, and her physician

was astonished. On the same day she was discovered giving herself an injection of morphine. She had hidden a syringe and a solution of the drug in her bustle.

"I have tried," she said, "every possible means to get along without the morphine, but it was impossible."

She left the asylum on April 22, 1888, in good physical condition, but returned on the 15th of October of the same year and was discharged on the 22d, only to return on the 26th of December. She left on the 5th of February, 1889, but again suffered from indulgence in the drug, and the following are the dates of subsequent admissions and discharges to Sainte-Anne:

Entered, October 4, 1889; discharged, October 26, 1889.

Entered, April 1, 1890; discharged, April 19, 1890.

Entered, March 6, 1891; discharged, May 23, 1891.

In 1891 she suffered a severe shock, caused by the death of her brother. He was found drowned.

"When I saw him at the morgue," she said, "I was like an insane woman; I wished to carry his body home; I refused to believe that he was dead; and on the day of his funeral I did nothing but laugh; I wished to sing all the time; it was all involuntary."

This tempestuous grief only served as a new spur to her old habit. She began using larger doses than ever.

"I wish to hear no more about a cure," she said, and, fulfilling her declaration, she kept away from the hospitals until the 26th of January, 1895, when she was forced again to seek admission to the Sainte-Anne Asylum. She suffered from highly depressing nightmares, had visual hallucinations, and saw imaginary people, such as a woman with a black veil, etc. She realized, however, that these visions were purely imaginary. She left the asylum on the 10th of November, 1895.

In speaking of her sufferings from deprivation of the drug, she said:

"This winter I was at death's door; I took almost nothing during six months, and for eight consecutive days I had absolutely nothing."

As soon as she left the asylum she again started her old practice of morphine injections and continued them until April, 1897. As she then fell into a very alarming condition, she began to diminish her doses, taking only twenty centigrammes a day. In conjunction with this, however, she also took five grammes of chloral and twenty grammes of laudanum daily. This caused insomnia and loss of appetite, and she again came to the Sainte-Anne on the 12th of April, 1897.

She then weighed but forty-four kilogrammes and eight hundred grammes. The method of progressive diminution was employed, and the treatment was finished on the 23d of April. She improved rapidly, and in July weighed three kilogrammes more than she did at the time of her admission. She was discharged on the 23d of July, 1897.

Coming from a highly neuropathic and psychopathic family, this patient had manifested from her very earliest age most prominent psychopathic symptoms. She had hysterical attacks, had attempted suicide, and could not accommodate herself to her surrounding circumstances. The appetite for morphine was only one prominent symptom of a disease based upon the deep root of degeneracy which she inherited from her ancestors.

In further illustration of this same class of degenerates, I would cite the following case of cocaineism and morphinism:

Georges B., twenty-six years old, born in Geneva, entered the Sainte-Anne Asylum on the 26th of March, 1897.

The patient's father was a man of high accomplishments, who died of an apoplectic attack. His mother died of heart disease. A grand uncle on the mother's side was somewhat neurasthenic.

The patient, although very intelligent, is singularly lacking in enterprise. During his varied career he exhibited a great lack of stability. In 1886 and 1887 he studied pharmacy; then he determined to change his vocation and began the study of medicine. He undertook the task of acquiring many languages, and as a result of some whim settled upon engineering as his career. He succeeded in becoming a civil engineer, and even obtained a position as such with a railroad company.

In 1889, while in Spain, he contracted syphilis, and subsequently suffered from blennorrhagia. In 1890, while in Malaga, Spain, he suffered considerably from a cystitis, for which his physician gave him a hypodermic injection of morphine. The dose, of from one to two centigrammes a day, was repeated, but had no immediate beneficent effect upon him. On the contrary, he only suffered from nausea and headaches. After a continuous use of the drug for some days, however, the unpleasant effect wore off by degrees, and he began to like its results.

"The more accustomed I became to the use of morphine," he said, "the more pleasant its effects became."

His physician eventually gave him a hypodermic syringe and a prescription for a morphine solution, thus enabling him to administer the injections whenever he felt the need of doing so; beginning with doses of from one to two centigrammes a day, which, as he put it, made him feel as if he were "floating on cotton." So pleasant was this sensation that he soon made the slightest provocation a pretext for administering to himself an injection. He used the drug for ameliorating the effects of the slightest fatigue or a headache, and particularly to "increase his mental activity." He continued these injections until 1893.

One day he had some unpleasant words with the family of his *fiancée*, which quite disturbed him, and upon his arrival home he immediately gave himself an injection of twenty centigrammes of morphine. This was the first large dose he had ever taken. His father died soon after, and the shock of grief was another occasion for the self-administration of a large dose of the drug. This time he gave himself twenty-five centigrammes. In describing the effects of this dose, he said that he felt strong arterial throbbing at the temples, heard singing and ringing in the ears, seemed to see a mist before his eyes, and now and then saw brilliant flashes of light.

In 1893 he lost all interest in his work and decided to try his fortunes in South America. He undertook the voyage, and went without his beloved drug for forty-five days, the time consumed in making the passage across. On his arrival in Chile, however, he found it difficult to make his living, and became considerably oppressed, ate badly and slept poorly. He rarely took the injections now because of his pecuniary difficulties, but on the occasions when he could afford to indulge himself he

gradually increased the dose until, in March, 1894, he found it absolutely necessary to take one gramme and twenty centigrammes a day. Meanwhile, he was gradually failing in health and losing both appetite and weight, as well as becoming more and more depressed.

He then attempted to rid himself of the habit by substituting sparteine, but failed in the attempt. He entered a hospital for treatment, but being unable to stand the method of sudden suppression in vogue there, he obtained his discharge. He then contracted typhoid fever, for which he was treated, during a period of four months, with opium, wine, and morphine. At the expiration of that time he found himself penniless, but managed to scrape together enough to procure morphine, the drug, as he put it, having "in more than one instance encouraged and sustained" him, lending him strength to "struggle against the thought of suicide." In June, 1895, he found himself with absolutely no means of procuring morphine, and while searching in his valise, with the hope of finding some remnants of a former supply, he chanced upon a bottle of cocaine, which he had at one time used upon the advice of a druggist as an antidote to morphine.

He had recourse to this drug "in order to sustain my strength, which was failing rapidly, and to calm my hunger for the morphine." Within the course of twelve hours he took a gramme and a half of Merck's cocaine, without the slightest poisonous effect. "I went out the following morning," he said, "much invigorated, although I had been fasting since the morning before."

Soon after this he became intimate with a druggist, who generously supplied him with both morphine and cocaine. At first he only took fifty centigrammes a day of each drug. In August, 1895, however, he obtained a position as chemist at the municipal laboratory at Valparaiso, where he remained four months. As he continued using both drugs he soon began to experience auditory hallucinations. At night he thought he heard his manager saying to him:

"Ah, ah! here you are, I see you; you are not working; you are giving yourself injections instead of doing your work!"

As he was poorly paid at the laboratory he decided to return to France, and arrived home in September, 1896. Here he stayed with his uncle, who supplied him with morphine and cocaine. "It was only humane," he said, to do this. But the patient was not satisfied with the small doses supplied him by his uncle, and soon started in selling his clothes to procure money with which to purchase the drugs.

Toward March, 1897, he totally lost his appetite and the ability to sleep, and began to exhibit delusions of persecution. He imagined that every one was ridiculing him, and was firmly impressed with the idea of every one's animosity toward him. An increase in the dose of the drug caused his delirium to become more active. On the evening of the 25th of March he imagined that he was pursued by enemies, and cried: "Help, help! Murder!" He ran to police headquarters, begging for protection.

When brought to the *Infirmier du Dépôt* he imagined that in fact were crawling under his skin.

At the *Sainte Anne* his hallucinations ceased after the first day. The method of progressive decrease was employed, and he was discharged cured in July, 1897.

Extracts from the Notes of G. R. "It is a common belief that the use of morphine induces vivid dreams and indescribably pleasant sensations, and that

those produced by the use of opium, as stated in the accounts of opium smokers in the East. . . . I have found that morphine calms, cools, and represses, progressively, any physical desires. It ends, even, by producing temporary sexual impotency. There is, in connection with the latter, a total indifference to the opposite sex, this indifference sometimes becoming an aversion. The male morphine eater never thinks of woman.

"Once the morphine becomes a daily necessity, it is also an irresistible, absolute, and sole passion, excluding any other satisfying agent of the senses, passions, or inclinations. Morphine admits of no rival. It temporarily suppresses all physical as well as moral suffering. It excites the intellectual functions, and causes a feeling of self-satisfaction that surpasses any other pleasant sensation.

"I have endeavored, at different times, to gradually diminish my daily doses, centigramme by centigramme, but I have soon found myself suffering from marked malaise, oppressive anxiety, and neuralgic headaches; my skin became covered with cold perspiration, and I yawned incessantly. I felt unable to move or to do anything whatsoever."

In speaking of the effects of the gramme to gramme and a half of cocaine, which he took daily in connection with his morphine, he says:

"These large doses of cocaine plunged me into a condition of drowsiness, hebetude, and ecstasy of a peculiar nature. I gave myself hundreds of hypodermic punctures, which caused me to lose a considerable amount of blood, for I made intravenous injections. I remained in a condition of stupor, hypnotized by the glittering of the needle and the syringe. Sometimes I even experienced cataleptic attacks, falling asleep in an upright position, both arms uplifted, holding the needle and syringe for hours at a time. Once I remained in such a position for four hours and did not feel the least bit fatigued when I regained consciousness.

"Sometimes I saw small, almost microscopic, animals, which ran back and forth upon my skin, and gave rise to a creepy sensation. My general sensibility became dull; I could not smell as well as usual. But my hearing became more acute than ever, and I at times heard with such intensity that the process became painful; the slightest noise became abhorrent, and I often stopped my work, crying for absolute quietness. I soon began to have hallucinations. The howling of a dog in the yard sounded like the voice of my employer, who seemed to be reproaching me. The cracking noise of a panel or window made me imagine that I was being watched, or was to be interfered with in taking my usual injections."

The high intellectuality of a subject does not exclude the possibility of his being a degenerate. M. Magnan, in his *Recherches sur les centres nerveux*, cites many cases of so-called superior degenerates who, while of a highly intellectual order, nevertheless exhibit most extravagant obsessions and impulses.

A lady of our acquaintance, of a highly cultured mind and nature, a subject to whom I was a pupil's her to chew unground wheat. This did not satisfy her craving; she became morose, restless, and unable to perform her daily task.

"I am not under tired of," she said, "but I am pivo

must chew the grain." She keeps a supply of wheat ready at hand upon her work table and no dictates of conventionality can interfere with her indulgence of her strange appetite. She looks upon it as a slight oddity, but the clinician realizes the importance of the symptom and its underlying fundamental hereditary causes.

The morphine eater's malady differs in no way from this clinical manifestation, except it be in form. There is here, as there, an underlying history of degeneracy, which is characterized by many a clinical feature, the predilection for morphine being the most prominent symptom in the former.

The question naturally arises, Are such patients curable? Certain it is that they improve under close supervision. Where, however, as demonstrated in the first case above quoted, the hereditary influence is quite marked, and the unknown anatomical lesion is, inferentially, pronounced, the instability of the mental equilibrium is such that a permanent recovery is almost not to be hoped for.

I desire to express my cordial thanks to M. Magnan for his courtesy and for permission to study and publish these cases.

THE OUTDOOR TREATMENT OF TUBERCULOSIS IN THE ADIRONDACKS.*

By J. A. WILDER, M. D.,

SARANAC LAKE, N. Y.

PHYSICIANS have for many years noted the beneficial effects of pure fresh air in the treatment of diseases of all types, acute and chronic, especially those affecting the air-passages, and since the gratifying results obtained in this line by Brehmer, founder of the sanatorium at G6rbersdorf, Walther, of Nordrach, Dettweiler, and others in Europe, and Trudeau and Bowditch in this country, a new impetus has been given in the medical world to this method of treatment of pulmonary affections, with the result that at present much more is being done to cure and eradicate tuberculosis than has ever before been accomplished. That no particular climate is necessary for the cure of this disease, although some are undoubtedly superior to others, is now agreed to by all authorities on the subject. That no one climate will prove beneficial to all cases, and that there are some patients who, either on account of feeble resisting power to the disease or the overwhelming virulence of their infection, will eventually succumb to it wherever they may go or however favorable the circumstances under which they are treated, are also self-evident, and that continuous life in pure air, wherever it may be found, is the essential, *par excellence*, so far as climate is concerned, in the treatment of pulmonary tuberculosis, are facts generally conceded by those who have given the

subject much attention. There can be no doubt that great good has been done for patients suffering from this disease by life in some of our western and southern States; but physicians should not overlook the fact that there is quite near at hand a large tract of country where fully as good results have been and are at present obtained in the cure of tuberculosis as in either the West or South, without the necessity of the patient severing home ties to any great extent, and making such a long, tiresome, and expensive trip into a new country. That persons suffering from pulmonary tuberculosis should, if possible, be cured in a climate similar in its characteristics to that in which they intend to spend the remainder of their lives is now a well-recognized fact, and for that reason also it seems to me that the Adirondacks are more suitable for patients whose homes are in the East than places of considerable elevation and very dry atmosphere, unless the patients intend to make such places their permanent homes. A moderate elevation is usually no contraindication to patients having cardiac lesions, functional diseases of the nervous system, or hemorrhagic cases, and a cool, stimulating climate seems to be superior, especially for incipient cases, to the more or less enervating effect of continuous life in a warm climate. That the majority of patients improve more rapidly in the Adirondacks during cold weather than during the summer, due in all probability to this point, can be readily seen by any one making inquiries about the subject, which controverts the traditional idea that cold is to be avoided by consumptives. The Adirondack plateau covers over three million five hundred thousand acres, the greater part of which is densely wooded with evergreens, besides a great variety of deciduous trees, and has an average elevation of about two thousand feet above sea level. The soil consists almost entirely of fine quartz sand through which all moisture leaches very rapidly, the underlying formation consisting chiefly of the igneous rocks. A great number of villages and small settlements are found scattered all through this part of the country, many of which are very seldom heard of in the outside world, and many others that are still used only as pleasure resorts. On account of my acquaintance with Saranac Lake and its vicinity, and the results of the open-air treatment that I have been able to observe there, my remarks will refer principally to that section, although I do not consider the climatic conditions there in any way superior to those of numerous other places in the Adirondacks.

This place is becoming more and more popular each year as a health resort to both physicians and patients, and at present affords better living facilities and more conveniences for invalids than most resorts of its size and kind. It has a population of about twenty-five hundred, is situated about a mile and a half from Lower Saranac Lake in the valley of the Saranac River, and has an altitude of about eighteen hundred feet. It is well

* Read before the Saratoga County Medical Society, December 16, 1898.

equipped with good hotels, boarding houses, and stores, and affords opportunities for various amusements. The temperature in summer rarely reaches 90° F., and the nights are always cool. In winter the average temperature during the day is about 20° F., causing the air and snow to be quite dry, the cold not being very noticeable on this account. The extreme cold occurs only at night, and reports of its intensity are often exaggerated.

About a mile and a half from the village is situated the Adirondack Cottage Sanitarium, the nature of which is so little understood by the profession, and the growth of which alone proves the virtue of climatic treatment in this location, that I wish to give a brief history of it and quote the methods and results of treatment there. The sanitarium was organized in 1885 through the efforts of Dr. Trudeau and several charitably inclined friends as a philanthropic institution, part of the expense being paid by the patients and the remainder received from contributions, and was the first institution of its kind in this country to be conducted on such principles. Only patients who are in poor or moderate circumstances financially, and who are regarded as either curable or capable of considerable improvement by the examining physicians, are admitted, and a large deficit, which gradually becomes larger each year as more patients are accommodated, is overcome by donations and subscriptions from persons who have become interested in the work and appreciate the good done by it. When the institution was founded, thirteen years ago, it consisted of three buildings having accommodations for nine patients. It has steadily grown, until now it forms alone quite a settlement, consisting of twenty-three buildings, mostly cottages, and is capable of accommodating about a hundred patients. It has now a small endowment fund and a free-bed fund providing for quite a number of patients. The cottages are all arranged on the same general plan, consisting of a reception room with from two to five bedrooms opening into it. Large open transoms are above each door, and also open from reception room to outside, thus insuring a open circulation of air when ventilators or windows of bedrooms are partially opened. The temperature in the cottages is kept rather low at all times, some being heated by stoves, but those more recently built by hot water. During the summer tents are used by many, both in and outside the sanitarium, stoves being provided for drying them in case of rain, life in them being for the majority both beneficial and enjoyable. However, I can not dwell on this subject at length, as I do not intend to give a full description of the institution. The fundamental principles of treatment consist of rest in the fresh air and nourishment; dress of all kinds occupying a decidedly inferior place, and regarded only as adjuncts.

Patients are required to stay out of doors from eight to ten hours a day, regardless of weather, and to choose

with cottages thoroughly ventilated during both summer and winter. It is remarkable how soon they become accustomed to this life, and how few colds are contracted by it. Only one case of lobar pneumonia has developed in the sanitarium since it has been in existence.

The majority of the patients become so hardened in a short time that they sit out on the cottage verandas voluntarily the greater part of the day, even during the coldest and most stormy days of winter, being at that time of the year warmly wrapped in furs and protected from the wind by glass windows on one side of the veranda or by screens that can be moved about at will. The clothing, of course, demands considerable attention, especially during the cold weather. Heavy, loose-fitting, woolen underclothes, usually of the so-called fleecy-lined variety, are found very satisfactory. Most of the fur coats used are quite long and have high collars for the protection of the neck and ears. Heavy felt leggings, with leather moccasins or felt shoes, are used for the protection of the feet and lower limbs when patients are walking about. When they are resting, these parts are further protected by wrapping them in blankets, some placing the feet in boxes containing warm soapstones. Sweaters are also worn by many of the men during this season of the year.

Care has to be taken that the clothing is sufficiently heavy to keep the patient warm without causing noticeable perspiration. During the summer months the clothing is about the same as that used in this latitude, except that woolen underclothes are generally worn. Nose breathing is practised by all patients, and its effect in alleviating catarrhal conditions is very noticeable. In non-febrile cases the patients are encouraged to take a moderate amount of exercise, but none to walk more than about two miles a day. Skating and other sports not requiring much exertion are allowed to a limited extent. Patients whose temperatures remain normal until late in the day, and then only rise to a slight extent, are also allowed to exercise, but are warned to stop if the temperature is exaggerated by it. Patients with continuous fever, or with decided elevation in the afternoon or evening, are kept as quiet as possible until the temperature falls to normal or quite near that point, and it is remarkable how soon this happens in most cases when the directions given are faithfully carried out. Carriage and sleigh riding are allowed freely, except to those having high temperatures or other symptoms of decidedly active disease. Horseback riding, wheeling, mountain climbing, and other forms of violent exercise are prohibited, as it has repeatedly been proved that much harm may result from the exertion of any kind. Breathless exercise, such as rowing and particularly arrested racing, is not allowed, as such exercise is still active.

The diet is composed of the best quality of food, fats and carbohydrates being used in moderation, and the

as this is another most important point in the treatment, particular attention is paid to the quality and preparation of the food. Meats of all kinds, eggs, milk, butter, the cereals, vegetables, and fruits are consumed in large quantities, and patients having no contraindications, such as disorders of digestion or high temperatures, have explained to them the necessity of taking large quantities of nourishment.

Instead of giving numerous light meals during the day, as is practised in some sanatoria, three regular hearty meals a day, with lunch in the evening for those who wish it, are given, except in febrile cases, when the patients receive nourishment more often. A great deal of milk is consumed between meals, patients taking it to their cottages and using it at will.

Cod-liver oil in moderate-sized doses, and creosote in the form of the carbonate in small doses, are given to some patients, but only continued with those who improve under its administration, being immediately discontinued as soon as the stomach begins to rebel or nutrition becomes faulty.

Arsenic and iron are used in cases in which there is much anaemia, the former seeming to be of special value to patients who are able to tolerate it. Different preparations of the hypophosphites are also used as tonics.

Night sweats seldom require medicinal treatment in the incipient cases here, or even in the more advanced cases, the outdoor life soon causing them to disappear. When they persist, a cool sponge bath containing a little alcohol at night is generally sufficient; if it is not, camphoric acid and atropine are used. For hæmorrhage, rest in bed, morphine, ice-bags, digitalis, and cracked ice by the mouth are used. In extreme cases ligation of the extremities is practised. For loss of appetite and poor gastric digestion, nux vomica and the mineral acids are mainly depended upon. For constipation, which is very frequently the result of superalimentation and lack of exercise, cascara sagrada or an iron, strychnine, and belladonna pill is usually given. For the cough, a menthol spray to the larynx and codeine are found to be most satisfactory. Alcohol in any form is seldom prescribed, as in the incipient cases it is usually unnecessary. Hydrotherapy is limited to the general warm bath and cool sponging. The latter, when used systematically, seems to assist greatly in the hardening process, besides stimulating the circulation and causing the patient to feel invigorated temporarily.

The treatment by inhalations is used only to a very limited extent. The pneumatic cabinet was used for several years, but, as no better results were obtained in patients taking that treatment than in those who simply sat out of doors, its use has been discontinued.

Quoting from a paper recently published by Dr. Trudeau in the *English Practitioner*, the results obtained at the sanitarium for 1897 and 1898 are as follows, patients not remaining more than three months not being included in the table:

"Number of patients treated, 203; average time of treatment, nine months.

Condition of patients when admitted.	Apparently cured.	Disease arrested.	Improved.	Unimproved.	Died.
Incipient 75	55	16	2	2	0
Advanced 84	15	38	19	11	1
Far advanced 44	0	7	19	13	5
Total 203	70	61	40	26	6

"The necessity of making an early diagnosis is emphasized by study of this table, which shows that, while not a single patient in the far-advanced class was cured, fifty-five, or seventy-three per cent., of patients in the incipient class, which represents the earliest stage at which the disease can be recognized, were apparently cured."

Outside the sanitarium the treatment is carried out with more or less faithfulness on the same lines, but for persons of limited means, who are often too ill to be admitted to the sanitarium, the living conditions are occasionally very unsatisfactory.

It will be seen by these facts that the cure of tuberculosis is best obtained by very simple means, but requires time, patience, and perseverance on the part of both physician and patient, and especially the hearty cooperation of the latter.

NOTE ON

OBLITERATION OF THE UMBILICAL VESSELS BY ELECTRO-HEMOSTASIS WITH THE SKENE FORCEPS, IN LIEU OF LIGATION.

By ROBERT L. DICKINSON, M.D.,

OBSTETRICIAN TO KINGS COUNTY HOSPITAL;
INSTRUCTOR IN OBSTETRICS AND ASSISTANT OBSTETRICIAN
TO THE LONG ISLAND COLLEGE HOSPITAL; SURGEON TO BROOKLYN HOSPITAL

THERE is a weak spot in obstetric antisepsis. It is not a little curious that we should deliberately elect sloughing and suppuration as the method of healing of an obstetric wound. It has occurred to the writer more than once that a late puerperal infection, or a septic process in the breast consequent on a fissured nipple, or the lack of union in a primary perineal repair, might have its cause in the decomposing umbilical stump. The process is a dry gangrene, the slough separating from the fourth to the fifteenth day, granulation continuing from seven to twenty days. Putrilage is occasionally found. Warmth, moisture, and pocketing favor sepsis. Few nurses have been trained to carefully make traction on the stump in the daily dressing, and, at the same time, draw back the skin folds so that every crease and cranny is exposed. Even with a dry pack of every crease with aristol or iodoform or other powder, we can not be sure that the wound is not contagious; under such a crust I have found pus. The nurse takes no special precautions to sterilize her hands every time she comes in contact with the abdominal regions of the

baby. In the smaller maternities, where the same nurse dresses cords and cares for the patient in labor, the risk is evident.

Other Methods of Ligation.—We may treat this stump as we do in other amputations, by making sure that there is no material left to undergo necrotic change. It ought not to be difficult to isolate the vessels at the junction of the skin and the amnion when the jelly of Wharton has been stripped out and ligate each vessel separately with catgut or very fine silk. Then the vessels could be cut off close to the ligature, the stump of the cord carefully dissected away along the skin edge, the skin closed over with a subcuticular silk suture, a drying powder dusted on, and a small pad of gauze applied. The adhesive strap and the binder would complete the dressing. Oozing from the capillaries that run a few millimetres into the cord should be easily checked by the suture and pressure.

Such a method would be feasible only in maternities, or in the hands of men used to clean surgery. The open method now in vogue insures good drainage. The closed method just described, unless undertaken in a trained and conscientious manner, would favor arteritis, phlebitis, or other dangerous infection of the navel. Even with the open method I have seen in consultation erysipelas, gangrene, phlebitis, and tetanus.

Another objection to the closed-in method is the skill required to treat a secondary hæmorrhage. With the usual procedure the nurse can readily arrest bleeding by a second ligature. If the cord is cut too short for this, the ordinary direction is that one should pass a hairclip pin through the abdominal wall and across the stump, slip in another at right angles to this, and tie beneath them. This is easy but crude. In maternity work the resident would open up the wound, find the bleeding vessel, and ligate it, even if it is retracted.

The main objection consists in the difficulty of delicate manipulation on a heaving belly wall.

Treatment of the Cord with Dr. Skene's Forceps.—The ideal method must accomplish three results. The vessels must be securely and permanently controlled; infection must be out of the question—must be impossible; and the danger of hernia reduced to a minimum. A procedure already beyond the experimental stage accomplishes all these results. Electro-hæmostasis with Dr. Skene's forceps is not a charring process nor a roasting process, but a drying process.* The vessel or the stump grasped in the bite of his instrument becomes within the space of half a minute to two minutes a white, horny ridge, comparable to the edge of one's finger nail in consistency and color. This edge does not slough, but promptly becomes reorganized. As Dr. Pryor has shown, water pressure applied to the vessel from behind will make it burst elsewhere, but not at the end thus treated.

I propose that in our maternities we give this method a trial. When the child is removed from its mother, the cord is caught in two Keith clamps and cut, but not ligated. The cord is stripped of its jelly at its base. A square of gauze five or six layers in thickness may be split up to its centre. The slit is passed about the stump, which lies at the apex of the V, and the cut sides are then lapped over, so that the skin of the abdomen is protected from any heat. This gauze should have been wrung out of some solution so that it is damp but not dripping. Or a perforated square of asbestos, sterilized by flaming, may be substituted. The jaws of the Skene clamp are vaselined, and the clamp is applied so that the edge next to the abdominal wall is placed at the junction of skin and cord. While the cord is drawn upward, the clamp is closed firmly to its last notch. The clamp is lifted away from the abdominal wall, and the current is turned on for about two minutes. A little bubbling will occur as the juices sizzle out. The amount of heat is said to be about 180° F. After the clamp is removed, the scissors should cut through the desiccated, flattened part of the cord rather close to the abdominal side so as to leave but a narrow ridge projecting. This part of the cord seized becomes organized tissue, and, I believe, will ordinarily retract without leaving a projecting button.

One can imagine two conditions to which this method would be inapplicable. Where there was any doubt whether a tiny umbilical hernia existed or not, it should not be used. Where the junction of skin and amnion was in a rather deep pocket in the abdominal wall, it is possible that one would not feel justified in putting traction enough on the cord to pull up its skin edge to the surface, so that the clamp could be applied and the shield used without burning the skin around it.

To imitate this method, though very imperfectly, in the absence of the Skene outfit, a pile clamp and a Paquelin cautery may be employed. The utmost care must be used, in order that the stump may be left dry, white, and horny, but nowhere must it be black or charred; otherwise sloughing will occur.

To theorize a little further, judging from the results after hernia operations—a sounder scar should result from either of the two methods here advocated than from the ordinary process of granulation.

NOTE.—Since the foregoing was written cases have been treated with striking results. They will be reported before the American Gynecological Society in May.

Racial Characteristics. M. Paolo Mantegazza (*Nuova Antropologia, Triest, 1897*, January 11th), in an attempt to study the racial characteristics of different nationalities, has summarized the consensus of opinion of five out of six races, and one each of the six with the following results: In the opinion of the other five, Italians are a thence and crafty, French, impressionable, inconstant, and easily alarmed, ingenious and enthusiasts; English, cold and self-reliant, hypocritical, and vainglorious; Spaniards, violent and vain-glorious; and Russians, neurotic.

FORMALIN

IN THE TREATMENT OF WHOOPING-COUGH.

By HOWARD S. OLLIPHANT, M. D.,
NEW ORLEANS.

For the past year I have been experimenting with a solution of formalin in the treatment of whooping-cough. The results have been so gratifying I am prompted to report them in the columns of your journal. From my experience I am fully convinced that formalin is as much of a specific for this most distressing and dangerous disease as mercury is for syphilis or quinine for malarial fever. This mode of treatment and results convince me of the purely local nature of the infection of pertussis. The literature of this disease advances the theory that the infection is first located in the fauces, the air-passages and general system becoming infected by the multiplication of the germs. I am thoroughly persuaded that the infection remains local and that the systemic effects are incidental and result from the exhausting cough peculiar to the disease. When fever is present it is doubtless due to some coincident inflammatory action rather than to the specific germ of the disease. This idea is fully borne out by the rapid disappearance of all symptoms of pertussis after the formalin treatment, which consists purely of local applications. Carbolic acid, menthol, and other germicidal agents have been used locally with marked beneficial results, and have been duly extolled by the profession, but I am the first, so far as I know, to use formalin in the treatment of whooping-cough. Formalin is recognized as one of the most powerful and efficient germicidal agents in purifying disease-infected premises, and I am convinced it is the remedy, *par excellence*, for the destruction of the germ of whooping-cough, whether located in a crevice of a room or on a part of the human anatomy, provided the remedy is properly applied.

Whooping-cough is considered to be self-limited, lasting six weeks or two months under the ordinary treatment. With the formalin treatment the duration of the severest cases was less than a week, and several cases, after three applications, were cured. The mortality of this disease is classed third in the list of dangerous diseases peculiar to children. The heavy death-rate is doubtless due to complications arising during its long and exhaustive course under the ordinary treatment. With the formalin treatment after the third application to the throat marked improvement was observed, and in one case a complete cure. I look upon pertussis as simply an infection of the fauces—a place perfectly accessible to disinfection, and therefore curable in a few days. Free emesis follows each application, thereby dislodging the germs as well as destroying them. In the first case I treated after this method the vomiting was so severe the mother became alarmed and called to see me about it. The solution was ordered diluted. Out of twenty cases treated with this remedy not one failed to be cured

in less than eight days. I have seen cases in consultations with a *confrère* who was much pleased with the treatment, and pronounced it a specific. In conclusion, I would warn against too strong a solution being used in cases of young and debilitated children.

2316 CAMP STREET.

Therapeutical Notes.

Antemetic Mixtures.—The *Gazzetta degli ospedali e delle cliniche* for February 2d attributes the following to Weglesworth:

R	Menthol	15 grains;
	Alcohol, { of each	600 "
	Syrup, {	
	Chloroform water	1,050 "

M.

A dessertspoonful every half hour.

For the vomiting of pregnancy and bilious vomiting the following are given:

R	Carbolic acid	from $\frac{1}{10}$ to $\frac{4}{10}$ grains;
	Chloroform	5 drops;
	Syrup, { of each	1,800 grains;
	Distilled water, {	
	Tincture of bitter orange peel,	q. s.

M.

A dessertspoonful every two hours. Some spoonfuls of water should then be administered from time to time.

A Mixture for Dry Bronchitis with Paroxysmal Dyspnoea.—The *Riforma medica* for February 6th gives the following:

R	Alcohol solution of nitroglycerin (one per cent.)	12 drops;
	Alcoholic nitric ether	225 grains;
	Solution of chloroform in alcohol (ten per cent.)	120 "
	Water	2,400 "

M.

A tablespoonful to be taken every three or four hours.

For Convulsive Cough.—The *Riforma medica* for January 28th gives the following:

R	Fluid extract of thyme	165 drops;
	Syrup	1,050 "

M.

Three to six dessertspoonfuls daily, well diluted.

An Irrigation for the Acute Angina of Children.—The *Riforma medica* for December 21st credits the following formula to Marfan:

R	Crystallized carbolic acid ...	10 $\frac{1}{2}$ grains;
	Oil of thyme	3 drops;
	Glycerin	450 grains;
	Water	1,500 "

M.

A Creosote Enema.—Martz (*Province médicale*, January 28th) gives the following formula:

R	Creosote	10 parts;
	Oil of sweet almonds	200 "

M.

S.: A tablespoonful as an enema, morning and evening.

THE NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by
D. APPLETON AND COMPANY.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, MARCH 4, 1899.

THE WORK OF THE MASSACHUSETTS VOLUNTEER AID ASSOCIATION.

THE organization of this association, planned apparently somewhat on the lines of the old United States Sanitary Commission of the civil war, was effected last May. The work attempted and accomplished by it during the recent war with Spain is set forth in a most interesting and satisfactory way in a publication entitled *The Medical Work of the Massachusetts Volunteer Aid Association during the Spanish War*, recently published in Boston, presenting contributions by Dr. Herbert L. Burrell, Mr. J. T. Boyd, Dr. E. H. Bradford, Dr. J. T. Bottomley, Mr. W. H. Seabury, Miss C. W. Cayford, Dr. E. G. Brackett, Dr. W. H. Prescott, Dr. James Booth-Clarkson, Dr. T. B. Shea, Dr. Myles Standish, Dr. J. B. Blake, Dr. F. G. Balch, and a number of committees and subcommittees.

Considerable space, naturally, is devoted to the association's hospital ship *Bay State*, and there are many instructive pictures that show her construction and her appliances. Dr. Burrell, Mr. Boyd (an engineer), Dr. Bradford, Dr. Bottomley, Mr. Seabury (the ship's volunteer purser), and Miss Cayford (who had charge of the nursing) all contribute articles on the ship and the service it performed, which was most excellent. It is interesting to note that the *Bay State* is said to be the first aid association ship that has ever been equipped under Article XIII of the Geneva Convention.

Miss Cayford concludes that patients who are seriously ill can not be nursed so efficiently on shipboard as on land. Contrary to her expectation, however, she found that seasickness did not appear to interfere with the patient's improvement; but it was hard on the nurses at times, as will appear by the following remark: "The bathing could be carried out without discomfort to the patient, but was more or less of a strain on the back of the nurse, and was an especially trying thing to do when the nurse was sick."

Miss Cayford's views on nurses' uniforms seem to us sensible and worthy of heed. "Pongee silk may have its uses," she says, "but a working uniform on shipboard is not one of them. If seasickness is due in part to a mental condition, no wonder so many of us were so ill on the first trip. A more forlorn, ridiculous, and

tesque—and to ourselves melancholy—uniform could not have been devised. The most practical thing for a nurse's uniform on board a hospital ship is a short skirt of fairly heavy material (like duck or denim), shirt waist with celluloid collar, and gingham aprons. The whole should be of some neutral color—blue, brown, or green, as very light or white clothing is unpractical on shipboard." This is no trifling matter. As we have before now insisted, the uniform of a soldier should be attractive as well as serviceable, and we are quite prepared to believe that the same thing is true of a nurse's uniform. We are glad that so good an authority as Miss Cayford has not hesitated to express herself on this point.

The association's work in Santiago is described by Dr. Brackett, and Dr. Prescott recounts his experience at Camp Wikoff. Dr. Prescott is not sparing of criticism, but evidently he writes in no spirit of unkindness. The physicians, he says, varied in ability and character, but their average was above what one would find in any large city. They ranged from the ass who "cut off the uvula of a patient suffering with diphtheria, that he might breathe more easily" (for which exploit he was discharged), up to such men as Nanerode, of Ann Arbor, Senn, of Chicago, and Delafield, of New York. On the whole, Dr. Prescott regards the camp as an ideal one, and he is sure that the water was not unwholesome to begin with and not contaminated up to the time that the use of filters rendered any possible contamination harmless. "Complaint has been made," says Dr. Prescott, "that taps were not sounded, salutes fired, nor sufficient attention paid to the dead. As the cemetery was within one hundred yards of the hospital, the cruelty and danger of taps and salutes can be readily appreciated. On one day there were seventeen deaths, and, if these ceremonies (proper and impressive though they be) had been performed, I believe that fifty more men would have died among the sixteen hundred patients then in the hospital as a result."

Dr. Booth-Clarkson tells the story of the *Bay State's* medical staff's experience in Puerto Rico, and a most interesting one it is, but we have not space to do more than mention it. The association's ambulance corps's service and adventures on the steamship *Leicester* are dealt with by Dr. Shea and Dr. Standish. Dr. Blake writes of the Massachusetts volunteers at Camp Thomas, and Dr. Balch describes the reception of the sick soldiers in Boston. Viewed from whatever standpoint we may take, the association's work appears in the highest degree efficient and commendable, and it is well that the record of it has been brought out in so agreeable a form.

HYDRAULIC DILATATION IN CONTRACTION OF THE BLADDER AND STRICTURE OF THE URETHRA.

In the *Canada Lancet* for February Dr. Hugh H. Young gives the results attained at the Johns Hopkins Hospital in the treatment of cystitis by means of intra-vesical irrigations by hydraulic pressure without the use of a catheter. Four cases are quoted, the cystitis being of thirty, ten, six, and fourteen years' duration respectively. All the cases showed excellent results, the capacity of the bladder being greatly increased in the course of treatment, in one case to sixteen times its initial capacity. The quantity of urine voided at one time was also multiplied many times, while the intervals between micturition became lengthened. There is considerable pain apparently dependent on the treatment. It is asserted that it is easy to irrigate the bladder without a catheter through very tight strictures, and in case of very large prostate, with a hydraulic pressure of seven feet. The atony of the bladder consequent upon paraplegia is also said to be combated by the "massage" of alternate distention and evacuation. The technique is as follows: A fountain syringe with an eight-foot tube and a special conical nozzle (to be obtained from Hynson & Westcott, of Baltimore) is used. The patient lying on his back, properly protected from wet, the fluid used (two per cent. boric-acid solution with the occasional use of a stronger antiseptic—*e. g.*, one to five hundred of silver nitrate, or one to one hundred and fifty thousand bichloride of mercury, is the author's recommendation) is allowed to play over the glans and retracted foreskin. Then the nozzle is crowded tightly into the meatus, holding the penis behind the corona between the thumb and finger, and the bag is raised to seven feet. When the sphincter gives way and the fluid begins to flow into the bladder, the bag is lowered to five feet, and the flow of fluid permitted to continue until considerable pain is felt. Then the nozzle is withdrawn and the fluid allowed to be voided. The patients soon learn to conduct their own irrigations without aid. The irrigations in the author's cases were repeated four times daily. The author cites his own cases in refutation of the opinion expressed in one of the latest works on genito-urinary surgery that such dilatation is useless and can not be too strongly condemned.

It would seem as though this treatment were worthy of more extended trial, due caution being observed. The author experimented with negative results, using a solution of methylene blue, to ascertain if any danger existed of the fluid being forced into the ureters.

MINOR PARAGRAPHS.

THE CONSCIENCE OF A CONSCIENTIOUS OBJECTOR.

THE *Gazette médicale de Paris* for February 4th gives the following incident as illustrative of the value of "conscientious" objections to vaccination in many instances. The new law in England demands that to obtain the protection of the conscience clause in the vaccination act it is necessary that the parent should present himself, within three months, before the magistrate, and claim exemption from the necessity of vaccination for his child on the ground that "in his conscientious opinion" vaccination would be prejudicial to the child's health. Many of the magistrates who believe in the efficacy of vaccination lose no opportunity of demonstrating the value of the applicant's idea of conscience. A father recently presented himself before Mr. Plowdin, the magistrate at Marlborough Street Police Court, London, claiming exemption for his child from vaccination. It transpired that he had exceeded the allotted time for making application by twenty-four hours. Notwithstanding this, the parent insisted on his right to exemption on the ground of "conscience." "What!" said the magistrate, "you talk to me of your conscience, and you have forgotten all this time what it required of you. Are you aware that I can impose six months' imprisonment upon you, and that with hard labor?" At this threat the applicant expressed his purpose of submitting. Then the magistrate said: "That shows how much your conscience is worth. You pretend to believe that vaccination would place your child's life in danger, yet you hesitate in fear of a few weeks' imprisonment to stand by your convictions. However, don't be alarmed. I will accept your declaration in spite of the delay, and fine you two shillings for default." It may be that after all, through the action of judicious magistrates, the conscience clause may ultimately exercise an educational effect upon the public mind among such as are merely led astray by crowd suggestion, and are not essentially fanatics.

THE SALE OF SECRET REMEDIES IN GERMANY.

We learn from the *Riforma medica* for February 1st that a recent decree of the German Minister of Internal Affairs imposes upon the sale of all secret remedies in Germany the same precautions and regulations as are in force regarding poisons and other dangerous preparations. This is a good move, and one well worthy of imitation in other countries, if it is limited to the restrictions named.

CIDER AS A GERMICIDE.

THE *Wiener medizinische Blätter* for January 19th cites Bodin's observations (*Revue scientifique*) to the effect that cider is destructive of certain pathogenic micro-organisms, including the bacillus of typhoid fever, and, hence, that the addition of contaminated water to the apple juice is not likely to spread disease. This he attributes to the malic acid present in cider, but Berthelot ascribes it to the aldehyde contained in it.

THE SURGERY OF THE SUPRARENAL CAPSULE.

IN a Greifswald inaugural dissertation O. Bartels (*Centralblatt für Chirurgie*, February 11th) reports a

case of a mulberry calculus as large as a pigeon's egg removed from the kidney by the extraperitoneal operation. The suprarenal capsule was found rather firmly adherent to all the surrounding structures except the kidney, and to have undergone a tumorlike enlargement. It was removed piecemeal and found to be typically tuberculous. There was no bronzing of the skin.

THE COMPARATIVE SAFETY OF ETHER AND CHLOROFORM ANÆSTHESIA.

In the December number of the *Nordiskt medicinskt Arkiv* Wanscher accounts for the fact that late German statistics do not agree with those of the English-speaking peoples as to the strikingly greater safety of anæsthesia with ether than that with chloroform by the remark that ether was introduced into German practice just at the time when laparotomy came into vogue, and was chiefly used in such grave operations.

THE DEATH OF "CAVENDISH."

The death is announced from London of Mr. Henry Jones, M. R. C. S., better known to the world as "Cavendish," the recognized authority on whist, than as a medical man. Mr. Jones had, however, for very many years abandoned the practice of his profession, but in helping to popularize innocent recreation he undoubtedly contributed toward the maintenance of the *mens sana* so inextricably associated with the *corpus sanum*.

ITEMS.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending February 25, 1899:

DISEASES.	Week ending Feb. 18, Week ending Feb. 25.			
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	15	1	18	7
Scarlet fever.....	155	16	170	18
Cerebro-spinal meningitis.....	0	3	0	0
Meningitis.....	210	9	217	3
Diphtheria.....	161	11	181	21
Whooping-cough.....	15	6	12	0
Tuberculosis.....	255	187	281	191
Small pox.....	0	0	0	0
Chicken pox.....	13	0	13	0

The Death of Mr. Thomas Cooke, F. R. C. S.—In the sudden death of Mr. Thomas Cooke, F. R. C. S., which is announced from London, a distinguished feature has passed from the teaching world of medicine in London. Mr. Cooke in 1870 founded a private school known as the London School of Anatomy and Physiology, and many American physicians who have put in a little time in London will remember it and the genial person of its founder and teacher. He met with great opposition for a long while, but so persevering, so conscientious, and so excellent was his work, an antagonist of the old school that the London School of Anatomy subsequently was empowered to sign up the necessary attendance of medical students on the anatomical course required by several qualifying bodies, in place of the regular anatomical schools belonging to the various medical colleges. He was related to all his work, and

respected by every one who knew him, and his loss will be widely mourned in all parts of the world; for his school was a rendezvous for foreign and provincial practitioners who, having time to spend in London, availed themselves of the opportunity to brush up their anatomy by actual practical work under his shrewd and insistent direction, or to take out a practical course of operative surgery on the cadaver.

Thrombosis and Embolism Post Partum.—Singer (*Archiv für Gynäkologie*, 1898, vol. lvi, p. 218; *Gazette hebdomadaire de médecine et de chirurgie*, January 29th) arrives, from a study of his own cases with others recorded in the literature of the subject, at the following conclusions: 1. The formation of thromboses is commonly indicated several days in advance of other symptoms by the progressive augmentation of the pulse rate, whose modification depends on the progressive development of the thrombus and on its resulting augmentation of the blood pressure. The graphic curve of these modifications is very characteristic. 2. On a typical curve of this kind we may see the temperature remaining the same as before, the pulse chart mounting progressively and attaining its maximum coincidently with the appearance of oedema, or the cord formed by the thrombotic or the pulmonary symptoms. At the same time the temperature rises; but while the elevation of the temperature does not last long, the pulse persists for several days at the height previously attained.

Lectures on Comparative Pathology.—We learn that Dr. Woods Hutchinson, of Buffalo, who is at present sojourning in London, has been invited to give a course of sixteen lectures on comparative pathology in the new Polytechnic and Graduates' College.

Marine-Hospital Service Health Reports.—The following cases of small-pox, yellow fever, cholera, and plague were reported to the supervising surgeon-general of the United States Marine-Hospital Service during the week ending February 25, 1899:

Small pox.—United States.

Los Angeles, Cal.....	Feb. 17.....	35 cases, 7 deaths, in all since date of outbreak. Origin believed to be Arizona. 25 cases in hospital.
Sacramento, Cal.....	Feb. 1-17.....	1 case.
San Diego, Cal.....	Feb. 19.....	1 " 1 death
San Francisco, Cal.....	Feb. 1-17.....	1 "
Washington, D. C.....	Feb. 15.....	1 new case
Washington, D. C.....	Feb. 16.....	1 " case
Washington, D. C.....	Feb. 21.....	1 " "
Prosboly, Kan.....	Feb. 16.....	21 cases in all
.....	1 case
.....	There have been 56 cases in 13 families, with 7 deaths
Carroll County, Mo.....	Feb. 1.....	1 case, 1 death
St. Louis, Mo.....	Feb. 1.....	1 " "
Chowan County, N. C.....	Feb. 16.....	1 " "
Columbus County, N. C.....	Feb. 16.....	1 " "
Cincinnati, Ohio.....	Feb. 16.....	1 " 8 cases, 8 deaths
Columbus, Ohio.....	Feb. 1-9.....	1 " 1 case
Philadelphia, Pa.....	Jan. 7-13, 21.....	1 case
Bedford County, Pa.....	Jan. 7-13, 21.....	1 " "
Lehigh Township, Pa.....	Jan. 7-13, 21.....	1 " "
Jackson, Madison County, Tenn.....	Feb. 11.....	1 " "

Plague.

Bombay, India.....	Jan. 17-24.....		456 deaths.
Calcutta, India.....	Jan. 7-14.....		2 "

Oil in the Treatment of Plague.—Dr. J. V. Ramaswamy Nayudu (*Indian Lancet*, December 16, 1898) calls attention to the ancient use of olive oil in plague, and the extensive evidence of its powers of prophylaxis. He says that Mr. Baldwin, the British consul at Smyrna, observed that out of nearly a million people who died of plague in Egypt in the space of four years, there was not a single oilman or dealer in oil. Taking this hint, he suggested unction with olive oil as a protective against plague. The method was first tried in 1792 when twenty-two Venetian sailors repeatedly anointed with the oil lived for five days with three infected persons (all of whom died) without a single individual catching the infection. Three Armenian families consisting of twenty-seven persons were saved from infection by adopting this precaution, though they lived in the same floor and constantly attended on plague patients. The nurses in the plague hospital at Smyrna were also thus effectually protected against infection. On the 14th of June, 1819, in answer to a question from a select committee of the House of Commons, Sir Brook Faulkner, physician to the forces at Malta, said that the military attendants at the pest hospital were protected against infection by wearing a dress of oiled silk. In 1891, Sir J. McGregor recorded in the medical sketches for the year that during the Egyptian campaign all men employed in applying oil to the feet of camels escaped the plague. Mr. Jaclon recorded in page 16 of a book on the *Commerce of the Mediterranean*, that the coolies

working in the oil stores at Tunis smeared themselves with oil and that they were rarely affected when the epidemic raged in the city.

The oil was subsequently tried as a curative in the early stage of the disease and was found to answer well; and for this purpose it was applied warm all over the body.

The Rev. Lewis, of Pavia, chaplain and agent to the hospital called St. Anthony's at Smyrna, after trying this oil for five years pronounced it to be the most efficacious of all remedies made use of during a period of twenty-seven years. His directions were simply these:

"Immediately after a person is perceived to be infected with plague, he must be taken into a close room, and over a brasier of hot coals, with a clean sponge dipped in warm olive oil, his body must be very briskly rubbed all over, for the purpose of producing a profuse sweat. During the friction, sugar and juniper berries must be burned in the fire, which raise a dense and hot smoke, that contributes to the effect. The friction ought not to be continued more than four minutes, and a pint of oil is enough to be used at each time. In general the first rubbing is followed by a very copious perspiration; but should it fail of this effect the operation may be repeated, first wiping the body with a warm dry cloth; and in order still further to promote perspiration, the patient may take any warm sudorific drink, such as elder-flower tea, etc. It is not necessary to touch the eyes; and other tender parts of the body may be rubbed more gently. Every possible precaution must be made use of to prevent the patient taking cold, such as keeping covered those parts of the body not directly under the operation; nor must the linen be changed till the perspiration has entirely subsided. The operation should be repeated once a day until evident symptoms of recovery begin to appear. If there are already tumors on the body they should be gently and more frequently rubbed till they appear to be in a state of suppuration, when they may be dressed with the usual plasters. The operation ought to be begun on the first appearance of the symptoms of the disease; if neglected till the nerves and the mass of the blood are affected or a diarrhœa has commenced, little hope can be entertained of cure; but still the patient should not be despaired of, as by an assiduous application of the means proposed some few have recovered even after diarrhœa had commenced."

Encouraged by the success which attended the external use of the oil in curing plague, it was tried internally. In 1829, two hundred persons were thus treated, and the remedy was found to fail in ten cases only.

The mode of administration was as follows:

As soon as infection was caught (this probably means as soon as symptoms of the disease appeared) four to eight ounces, according to the strength of the constitution, were given to the patient. This produced profuse sweating, which seemed to expel the poison. The sudorific action of the drug was aided by taking decoction of elder berries (*Sambucus nigra*). The oil in some cases acted as an emetic, in others as a purgative, but profuse perspiration was a general rule and the most favorable sign for recovery. The efficacy of the drug was so great that the Moors, who were generally averse to taking any medicine internally, especially for plague, readily took to it. In a village near Tangier a father who had lost his wife and four children by plague adopted this treatment and saved himself and four other children. To render the drug more efficacious the oil was subsequently used both internally and externally

Incisions into the Hairy Scalp.—Dr. George H. Monks (*Boston Medical and Surgical Journal*, February 16th), noticing the fact that scars in the scalp often seemed to be unduly broad, as the result of careful investigations concludes that this result is due to the nature of the incision (whether accidental or purposive) and its relation to the direction of the hair root. He advises, therefore, that whenever it is necessary to make an incision into the hairy scalp in the back of the head, and especially when it is particularly desirable to conceal the scar, the knife should be held in a position at right angles to the surface of the skin where a vertical incision is to be made, but in a position oblique in reference to the skin whenever a transverse incision is contemplated. That is to say, as the knife passes into the scalp the blade should be kept parallel to the course of the hair so as not to divide them. The same principle, says, may also find its application in the treatment of scalp wounds, whenever it becomes necessary to close the raw edge of the wound before stitching them together.

The Prurigo of Pregnancy.—At a recent meeting of the French Society of Dermatology and Syphilography M. Gaston (*Gazette hebdomadaire de médecine et de chirurgie*, February 16th) drew the attention of the society to the existence of a prurigo of which he had made a special study with Dr. Cathelin-au. The predominant localization of this prurigo, he said, was upon the arms and thighs, and it supervened on pregnancy in patients previously free from any similar manifestation. It was unaccompanied by any bullous lesions. M. Gaston contrasted this prurigo with herpes gestationis, and mentioned the existence of an analogous affection accompanying uterine troubles apart from pregnancy.

The Medical Society of City Hospital Alumni, of St. Louis.—The programme for the meeting on Thursday evening, the 2d inst., contained the following titles: The Surgical Treatment of Chronic Empyema, by Dr. Francis Reeder; A Report of a Case of Cerebral Haemorrhage with Temporary Glycosuria, by Dr. R. B. H. Gradwohl; and Multilocular Ovarian Cyst, by Dr. Henry Jacobson. The subject for discussion at the meeting on the 16th inst. will be The Medical Inspection of School Children and the Hygiene of Schools.

The New Editor of the Journal of the American Medical Association.—The *Journal* for February 25th announces that Dr. George H. Simmons, of Lincoln, Nebraska, has been elected its editor. We wish Dr. Simmons all possible success in his new career.

An Antivivisectionist Quarrel.—*Science* for February 21th says that a suit is being brought by the treasurer of the New England Antivivisection Society to prevent the former president from disposing of the funds of the society. A law-suit, adds *Science*, is, perhaps, the most innocent disposition that could be made of these funds.

A Prize in Memory of Dr. Hermann Müller.—We learn from *Science* for February 24th that the Vienna Medical Club has voted the sum of three hundred golden crowns for the establishment of a prize in memory of Dr. Hermann Franz Müller, who recently died of plague contracted in the bacteriological laboratory of Vienna.

Changes of Address.— Dr. A. McNeil Blair, to No. 221 Prospect Avenue, Buffalo; Dr. M. L. Carr, to No. 353 West Fifty-seventh Street, New York; Dr. A. H. Hulsizer, to No. 1514 North Fifteenth Street, Philadelphia; Dr. Ruel B. Karbe, to Hotel Majestic, New York; Dr. William E. Thomas, to No. 18 Hanson Place, Brooklyn.

Army Intelligence. *Official List of Officers in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 18 to February 28, 1881.*

ARMSTRONG, LUCY M., First Lieutenant, U. S. Assistant Surgeon, U. S. Army, Department of the Interior, U. S. Office of the United States.

BAVISTON, JOHN M., Moderator. Since 1961, he has held
 as a member of the Executive Committee of the National
 Council of the World Council, N.Y. Mr. BAVISTON is
 a member of the Executive Committee of the World Council
 since 1961.

CLARK, MARGARET M., Secretary. She is a member of the
 Executive Committee of the World Council, N.Y. Since 1961
 she has held the position of Secretary of the Executive
 Committee of the World Council, N.Y.

DUVAL, DOUGLAS F., First Lieutenant and Assistant Surgeon, is detailed as a member of the board of officers appointed to meet at West Point, N. Y., March 1st, for the examination of candidates for admission to the Military Academy.

FISHER, HENRY C., Captain and Assistant Surgeon, is relieved from further duty at Plattsburgh Barracks, N. Y., and will proceed to Madison Barracks, N. Y., for duty, to accompany the Ninth Infantry to Manila.

FORD, CLYDE S., First Lieutenant and Assistant Surgeon. His resignation of his commission as First Lieutenant and Assistant Surgeon, Fourth Volunteer Infantry only, is accepted.

HEG, ELMER E., Major and Brigade Surgeon, will proceed to Havana and report to the commanding general for duty.

MUNN, CURTIS E., Major and Surgeon, and SMITH, LOUIS P., First Lieutenant and Assistant Surgeon, are detailed as members of the army retiring board appointed to meet at Denver at the earliest practicable date for the examination of such officers as may be ordered before it.

WYETH, MARLBOROUGH C., Major and Brigade Surgeon, will proceed to Havana and report to the commanding general, Division of Cuba, for duty in charge of the medical supply depot to be established in the vicinity of the city of Havana.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the United States Marine-Hospital Service for the Fourteen Days ending February 25, 1899:*

KINYOUN, J. J., Passed Assistant Surgeon. To proceed to Albany, Ga., for special temporary duty. February 18, 1899.

WERTENBAKER, C. P., Passed Assistant Surgeon. To rejoin station at Wilmington, N. C. February 20, 1899.

BREADY, J. E., Acting Assistant Surgeon. Granted seven days' extension of leave of absence from February 9, 1899. February 18, 1899.

GERRISH, W. H., Acting Assistant Surgeon. Granted leave of absence for thirty days on account of sickness. February 18, 1899.

O'REILLY, W. J., Acting Assistant Surgeon. Granted leave of absence for two days from February 28, 1899. February 16, 1899.

PHILLIPS, E. L., Acting Assistant Surgeon. Granted leave of absence for fifteen days. February 18, 1899.

Resignation.

PHILLIPS, E. L., Acting Assistant Surgeon. Resignation accepted as tendered, to take effect upon the appointment and qualification of his successor. February 9, 1899.

Society Meetings for the Coming Week:

MONDAY, *March 6th:* New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morristania Medical Society, New York (private); Brooklyn Anatomical and Surgical Society (private); Corning, N. Y., Academy of Medicine; Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; St. Alban, Vermont, Medical Association; Providence, Rhode Island, Medical Association (annual); Hart-

ford, Connecticut, Medical Society; South Pittsburgh, Pennsylvania, Medical Society; Chicago Medical Society.

TUESDAY, *March 7th:* New York Neurological Society; Buffalo Academy of Medicine (Section in Surgery); Elmira, N. Y., Academy of Medicine; Medical Society of the County of Herkimer, N. Y. (annual—Herkimer); Hudson, N. J., County Medical Society (Jersey City); Androscoggin, Maine, County Medical Association (Lewiston); Essex, Massachusetts, South District Medical Society (annual—Salem); Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore).

WEDNESDAY, *March 8th:* New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Society of the Alumni of the City (Charity) Hospital; Society for Medical Progress, New York; Medical Societies of the Counties of Albany and Montgomery (quarterly), N. Y.; Pittsfield, Massachusetts, Medical Association (private); Worcester, Massachusetts, District Medical Society (Worcester); Philadelphia County Medical Society.

THURSDAY, *March 9th:* Society of Medical Jurisprudence and State Medicine, New York; Brooklyn Pathological Society; The Jenkins Medical Association, Yonkers, N. Y.; Medical Societies of the Counties of Cayuga and Cortland (quarterly), N. Y.; South Boston, Massachusetts, Medical Club (private); Pathological Society of Philadelphia.

FRIDAY, *March 10th:* Yorkville Medical Association, New York (private); Brooklyn Dermatological and Genito-urinary Society (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties, N. Y.

SATURDAY, *March 11th:* Obstetrical Society of Boston (private).

Births, Marriages, and Deaths.

Born.

MILLIKEN.—In Dallas, Texas, on Friday, February 10th, to Dr. and Mrs. Samuel E. Milliken, a daughter.

Married.

ALLEN—BELL.—In Lake Providence, Louisiana, on Monday, February 20th, Mr. T. W. Allen and Miss Della Bell, daughter of Dr. William D. Bell.

BLAIR—ANDERSON.—In Marion, N. Y., on Wednesday, February 15th, Dr. A. McNeil Blair, of Buffalo, and Miss Josephine Caroline Anderson.

COOKE—WEST.—In New York, on Thursday, February 16th, Dr. Henry Arnold Cooke, of Boston, and Miss Bertha Helen West.

JARRATT—TAYLOR.—In Port Gibson, Mississippi, on Thursday, February 16th, Mr. Bernard E. Jarratt, son of Dr. Ashbury L. Jarratt, of Horn Lake, Mississippi, and Miss Julia Taylor.

KARIBE—NOBLE-EARLE.—In New York, on Thursday, December 22, 1898, Dr. Ruel Bidwell Karibe and Mrs. Clara Noble-Earle.

PENNIG—EISCHIN.—In Buffalo, on Wednesday, February 23d, Mr. Frank L. Pfennig and Miss Anna Eischen, daughter of Dr. David C. Eischen.

THOMSON—FREEMAN.—In Savannah, Georgia, on Monday, February 20th, Dr. Edgar S. Thomson, of New York, and Miss Martha Shelman Freeman.

VAN ARSDALE—WHITE.—In New York, on Tuesday, February 21st, Dr. William Waldo Van Arsdale and Miss Edith May White, daughter of Dr. Whitman V. White.

Died.

BENHAM.—In Hudson, N. Y., on Sunday, February 19th, Dr. John C. Benham, in the eighty-third year of his age.

CUTTER.—In New York, on Sunday, February 19th, Mrs. Rebecca S. S. Cutter, wife of Dr. Ephraim Cutter.

DAY.—In Newfoundland, N. J., on Wednesday, February 23d, Florence Elizabeth Day, daughter of Dr. Edward A. Day, of Brooklyn.

HEACOCK.—In New York, on Friday, February 24th, Dr. Willard Avery Heacock, in the thirtieth year of his age.

HEWITT.—In Hoosick Falls, N. Y., on Saturday, February 18th, Dr. Clifford Hewitt, in the forty-fourth year of his age.

KEANE.—In New York, on Tuesday, February 21st, James F. Keane, son of Dr. J. J. Keane, in the twenty-first year of his age.

STONE.—In Savannah, Georgia, on Sunday, February 19th, Dr. George H. Stone.

WARD.—In Brooklyn, on Saturday, February 25th, Dr. John E. Ward, of Coney Island, in the fifty-fourth year of his age.

Obituaries.

George H. Stone, M. D., of Savannah.—The death of Dr. Stone, which occurred on February 19th, removes from the Southern medical profession a well-known and highly accomplished practitioner. He was looked upon as a yellow-fever expert, and in the epidemic of 1876 in Savannah he did notable service. Dr. Stone was born in Albion, N. Y., and graduated in 1868 from the medical department of Georgetown University. During the War of the Rebellion he served with the Northern forces, and settled in Savannah in 1873. For two years he was president of the Georgia State Medical Society.

Special Articles.

THE LAW IN ITS RELATIONS TO PHYSICIANS.

By ARTHUR N. TAYLOR, LL. B.

VIII.

CONTRACT OF PATIENT WITH PHYSICIAN.

(Continued from page 301.)

Contract Implied on the Part of the Patient. A contract on the part of the patient, as well as on the part of the physician, is created by law. Such contract, like the one of the physician, is based upon and grows out

of the relations of the parties, and is in its nature complementary to the contract of the physician.

Contract to Pay Physician's Fees.—The right of the physician to charge and recover compensation for his services is very seldom the subject of an express agreement between the physician and patient; yet the physician is quite as secure in this right as though it were fixed by formal agreement, it having been long settled that where a person avails himself of the benefit of services done for him, even though without his positive authority or request, the law supplies the formal words of contract and presumes him to have promised an adequate compensation. It may therefore be laid down as a general rule that whenever a patient employs or receives the services of a physician he is bound to pay a reasonable compensation for such services.*

A notable exception to this rule formerly existed under the law of England, which treated the services of the physician as honorary and gratuitous, and did not permit him to recover a compensation therefor unless the patient was bound by a special agreement to pay. The services of the surgeon were not considered of the same honorary character, and he was therefore able to recover his fees without a special agreement. Under the medical act passed in the twenty-first and twenty-second years of the reign of Victoria, physicians, if duly registered, are entitled to recover reasonable compensation for their services without any express contract providing for such compensation, thus being placed on the same footing in this regard as physicians in the United States.

Liable for Subsequent Visits.—It will be remembered that a physician undertaking the treatment of a case is bound to continue his visits as long as the condition of the patient requires his attention. The counterpart of this obligation may be found in the implied contract which the law creates requiring the patient to pay the physician not only for the first visit, which he has expressly requested, but for all further visits or services which the physician and surgeon makes or renders by reason of the necessities of the case.†

Liable for Fee of Consultant.—The patient is bound not only to pay the attending physician, but also the physician who is called to a consultation, and this has been held to be the law notwithstanding there is an agreement between the attending physician and patient that the attending physician shall pay the expenses of such consultation‡.

The reason for this rule may be readily seen. It has been observed that where a party knowingly and without objection permits another to perform services for him, the law implies a promise to pay what the services are reasonably worth. Consequently, when a physician is called to a consultation, even though it be by the attending physician, it is fair for him to presume that the consultation is for the benefit of the patient, and to rely upon the promise of payment which the law makes for the patient. The agreement of the attending physician to pay the consultant is unusual and exceptional, and being contrary to the ordinary presumption of law the consultant will not be bound unless he has notice of such arrangement.

It is doubted, however, whether a patient is bound by an implied contract to pay for medical services of a

‡ Sheldon v. Johnson, 40 Iowa, 84; Green v. Stadler, 6, Wis. 517.

physician called in by her attending physician for the mere purpose of convincing her that he is doing all that can be accomplished for her, where such physician, in fact, rendered no services for her and was not called in at her request.*

It is pertinent to state at this point that should the patient be required to pay the consulting physician after the attending physician has agreed to defray this expense, the patient may recover the amount so paid by him from the attending physician, or he may treat it as a counterclaim and deduct the amount from fees earned by the attending physician.

Contract of Obedience.—It is a well-settled proposition of law that it is the duty of the patient upon placing himself in the hands of a physician to follow strictly all instructions and conform to the necessary prescriptions and treatment, if they are such as a physician or surgeon of ordinary skill and care would adopt or sanction. As a disregard of this obligation results to the injury of the patient only, it does not give the physician a cause of action against the patient; yet if the patient endeavors to recover damages from the physician for injuries which he maintains result from unskilled treatment, the physician and surgeon may, by showing that the patient is guilty of such negligence or disobedience, prevent his recovery.†

Sunday Contracts.—In the absence of statutes to the contrary, any contract executed on Sunday is as valid and binding as though executed on a week day. Each State has, however, passed laws requiring the observance of Sunday. In all States labor is prohibited, and in most States the transaction of business is made unlawful upon the Sabbath. In those States which go so far as to prohibit labor only, one is free to enter into contracts and to execute promissory notes and other instruments which are perfectly valid; but in those States which prohibit the transaction of business, any instrument or contract made or entered into on Sunday is invalid and can not be enforced even though one of the parties may have performed his part of such contract. If, for instance, goods are sold and delivered on Sunday, or services are rendered on that day, the party receiving the goods or enjoying the benefit of the services is under no obligation to pay for them.

These statutes, however, unanimously except from their operation contracts made to carry out works of necessity or charity, and the courts have held, whenever the question has been raised, that the contract of the physician falls within this exception, and that it is binding in all respects both upon him and upon the patient.‡

Letters to the Editor.

A HOSPITAL FOR ACUTE CASES OF INSANITY.

BROOKINGDALE ASYLUM, WHITE PLAINS, N. Y.,
February 20, 1899.

To the Editor of the New York Medical Journal:

SIR: The subject of a hospital for acute and recent cases of mental disturbance, situated in New York city

and near the medical schools, is not a new one, but it appears that now from various directions the subject is again being approached. The desirability of such a hospital can hardly be doubted if the practical difficulties can be met. It should, I think, be a public hospital, and no particular coterie of medical men should monopolize its advantages, but it should be open to all, in order to obtain public recognition and support. Another advantage of a public hospital would be that the responsibility for restricting the liberty of certain patients, who undoubtedly would require that such an authority be at times exercised, would not be assumed by individuals, but by the State, which stands as the protector as well as the custodian of such sufferers from mental disease as are incapable for the time of exercising a proper judgment and self-restraint. If a new departure in the direction of a hospital for such cases of mental disturbance as may be transitory in their nature is established, it should have the support and authority and protection which the representatives of the State in this department of public charity could give it.

The practical difficulties, while not small, are not insuperable, and could be overcome if public spirit and professional unselfishness characterized the effort. The State now has a central institute for investigating the causes of insanity. The president of the State commission in lunacy, who is in close touch with the institute, is well acquainted with insanity in all its clinical manifestations. Were this institute in close proximity to a hospital devoted to acute and often transitory attacks of insanity, there might result from the State expenditure of money a mutual advantage to the hospital and to the central investigating institute.

The practical difficulties include a place for these joint and closely related efforts. No special size or shape of rooms is necessary in treating insanity, though certain advantages are obtained in suitable hospitals; but for a trial of a new combined hospital for transient cases, none to remain long, and contiguous space for the work of the pathological institute, temporary accommodations might be found, without waiting to build at public expense, or for some philanthropist to open his heart and his pocketbook. Large buildings are constantly being abandoned, like the New York College building, the old Columbia College, the Woman's Hospital, etc., part of one of which might be temporarily obtained for an experiment of the kind referred to. If it became a great success, suitable accommodations could come later. As a temporary provision for a certain number of insane persons, it would bring relief to the present inadequate provision for them, and would to some extent do away with the present imperfect provision for urgency cases at Bellevue Hospital; and it would be a distributing point for chronic or unsuitable cases to the present public and private establishments.

Such a combined hospital and psychopathological laboratory, centrally and wholesomely situated, where economy and efficiency had their proper relation, would have a distinct hospital work of great value, and would give facilities for clinical teaching and higher investigation regarding insanity which can hardly be overestimated, facilities at present conspicuous by their absence on account of the practical inaccessibility of the present hospitals for the insane to the medical students.

A valuable editorial on this subject appeared in the New York Sun of February 19th.

SAMUEL B. LYON, M. D.,
Medical Superintendent.

Book Notices.

A Text-book of Obstetrics. By BARTON COOKE HIRST, M. D., Professor of Obstetrics in the University of Pennsylvania. With Six Hundred and Fifty-three Illustrations. Philadelphia: W. B. Saunders, 1898. Pp. 14 to 846.

IN this work the subject is divided into seven parts, as follows: Pregnancy, the physiology and management of labor and of the puerperium, the mechanism of labor, the pathology of labor, the pathology of the puerperium, obstetric operations, and the newborn infant. The first three parts are well written and contain all that the student will require, but two parts on the pathology of labor and of the puerperium, while being full and up to date in certain respects, are far too meagre in others.

The illustrations throughout the book are original and for the most part particularly good. The chapters on obstetric operations are admirable in text and illustrations. The closing chapters are devoted to the physiology and pathology of the newborn infant, and they cover the subject fairly well. While, as a text-book, Dr. Hirst's treatise may not be an improvement over one or two of those already adopted in our medical schools, as an addition to the obstetrician's books of reference we can heartily recommend it.

Diseases of Women. A Treatise on the Principles and Practice of Gynecology for Students and Practitioners. By E. C. DUDLEY, A. M., M. D., Professor of Gynecology, Northwestern University Medical School, etc. With Four Hundred and Twenty-two Illustrations, of which Forty-seven are in Colors, and Two Colored Plates. Philadelphia and New York: Lea Brothers & Co., 1898. Pp. xi-637.

FROM an author of Dr. Dudley's mature and rich experience and vigorous individuality one would hardly expect a work which would not be both profitable and interesting. The book which he has produced justifies the expectation, and this, be it remembered, at a time when there is no dearth in the production of excellent and satisfactory treatises on gynecology. The author has diverged somewhat from the usual lines in the plan of his work, considering the subject under five pathological heads or divisions—viz.: I. General principles. II. Inflammations. III. Tumors, malformations, and fetal pregnancy. IV. Traumatism. V. Displacements and pelvic massage. This arrangement is not altogether satisfactory, for it would manifestly be quite impossible to adhere strictly to it.

The changes in procedure which have marked the progress of gynecology in the hands of experienced and thoughtful men are to be noted in the chapter on local treatment. Routine measures, swabbing the vagina, applications to the interior of the uterus, the indiscriminate employment of pessaries have had their day, and a more, more direct therapy is prevailing. This is emphasized by the author, and if such a plan has diminished the number of visitors to the consultation room, it will be added to the good of the community in more ways than one, and has placed our art upon a more scientific and rational basis. In the matter of dilatation of the uterus, we would suggest that the description of the method for that purpose might henceforth be omitted from the text-books. With the means for rapid instrumentation of dilatation which are available, tents, of whatever material

composed, are practically obsolete, and they offer greater opportunities for mischief in the average case than instrumental dilators.

The chapters on the various forms of metritis are clearer, more logical, and more sensible than are to be found in some of the other text-books on gynecology. The development and diffusion of pelvic surgery have had much to do with the removal of this pathological stumbling-block.

The descriptions of surgical techniques are clear, concise, and forcible. There is seldom any doubt as to the author's meaning, and he reaches it by direct and forcible statement, as one would expect who has ever been brought into personal contact with him.

Why was the long chapter on pelvic massage placed at the end of the book? Did the author half or more than half agree with many of his *confreres* that this measure, like some others which have promised much, was passing?

Renal Growths; their Pathology, Diagnosis, and Treatment. By T. N. KELYNACK, M. D. (Vic.), M. R. C. P. Lond., Pathologist, Manchester Royal Infirmary, etc. With Ninety-six Illustrations. Edinburgh and London: Young J. Pentland, New York: The Macmillan Company, 1898. Pp. xiii-269. [Price, \$4.]

DR. KELYNACK has presented us with an interesting monograph upon a subject which from the standpoint of the pathologist is one of the highest interest, but of extreme difficulty. This is the first systematic treatise upon tumors of the kidney which has yet appeared in English, and the author's main pretension is "to indicate the work already accomplished and to suggest lines for further research."

This he has accomplished exceedingly well, but it is fair to say that his personal contribution to the subject is not great. The book is largely a compilation of the clinical histories and pathological findings of the more recently reported cases of renal tumors. The recorded observations of the older surgeons and pathologists are, unfortunately, almost valueless for scientific comparison, for the classification and nomenclature employed by them were indefinite and confused.

Dr. Kelynack has done good service in his industrious collection of the records of many well-studied cases, and his interesting and suggestive book is a welcome contribution to our meagre knowledge, for it renders easily accessible a large amount of valuable information, and judiciously reflects much that belongs to a better past.

The subject is treated chiefly from the point of view of the pathologist, though the clinical aspect of the matter is always held in view, and symptoms, signs, and diagnosis are fully discussed.

The chapter upon treatment, possibly the most original exposition of the subject, is composed of a large series of well-illustrated cases, each with an emphatic opinion regarding the best mode of treatment, early and radical, or conservative.

It will be a long time before the author's individual authoritative treatment can be generally accepted and written. In the chapters upon the pathology of the various renal tumors, the descriptions of the gross and microscopic changes, and of the clinical course of the disease, are well known to the student and the practitioner.

Principles of surgery, and of the treatment of the

quent during infancy and early childhood and even in prenatal life. These facts argue a close relation with developmental faults.

A logical classification of renal tumors must lean upon their embryogeny, and a formal treatise devoted to them demands a more exhaustive consideration of the embryonic development of the kidney than the author has afforded us. In this respect the book is a disappointment. The classification adopted is one based upon histological structure, but the author has fallen into some curious inconsistencies. For instance, the tumors of the adrenal are grouped with the adenomata, although he considers, strangely enough, that the adrenal is of strictly mesoblastic origin. The possibility that certain tumors hitherto referred to the sarcomata should be attributed to endothelial proliferation is briefly mentioned, but the subject is not further developed.

The writer is a pathologist, but pathologists will not find that he has thrown much light upon their difficulties.

The book is beautifully published and profusely illustrated with photographic reproductions which show gross appearances unusually well. There is an exhaustive bibliography.

Tropical Diseases. A Manual of the Diseases of Warm Climates. By PATRICK MANSON, M. D., LL. D. (Aberd.), Fellow of the Royal College of Physicians, London, etc. With Eighty-eight Illustrations and Two Colored Plates. New York: William Wood and Company, 1898. Pp. xvi-607.

"A MANUAL on the diseases of warm climates, of handy size, and yet giving adequate information, has long been a want; for the exigencies of travel and of tropical life are, as a rule, incompatible with big volumes and large libraries. This is the reason for the present work. While it is hoped that the book may prove of practical service, it makes no pretension to being anything more than an introduction to the important department of medicine of which it treats; in no sense is it put forward as a complete treatise, or as being in this respect comparable to the more elaborate works by Davidson, Scheube, Rho, Laveran, Corre, Roux, and other systematic writers in the same field."

Thus says the author in the preface, and we quote it at length because it seems to us to describe the work well. For the rest, it may be said that the book comprises seven sections, or parts. The first treats of tropical fevers; the second, of general diseases whose nature is unsettled, such as beriberi and the sleeping sickness; the third, of abdominal disease, the most important of all being cholera; the fourth, of the infective granulomata; the fifth, of animal parasites and the ills with which they are connected; the sixth, of skin diseases of warm climates; and the seventh, of local diseases whose nature is uncertain, *anthrax* for example.

We can not too warmly commend the book, for it is of an arrangement and size admirably fitted to fill the place of which the preface speaks, and, moreover, the material has been well sifted and clearly presented throughout. The work, it is true, is not exhaustive, but it is by no means meagre, and many a more pretentious volume contains far less of the valuable and the useful. It may be held that we as practitioners in a temperate clime have no need of works which treat of diseases of the tropics, but if such a statement were to be made it would need no serious consideration and certainly no rebuttal. Clearly the field this work covers

is one in which all serious-minded medical men should have ample knowledge and information. For the use of such as these we can suggest no source more generally useful than the work before us.

A Manual of Surgery for Students and Practitioners. By WILLIAM B. ROSE, M. B., B. S. Lond., F. R. C. S., Professor of Clinical Surgery in King's College, London, etc., and ALBERT CARLESS, M. S. Lond., F. R. C. S., Senior Assistant Surgeon to King's College Hospital, etc. New York: William Wood & Co., 1898. Pp. viii-9 to 1162.

WHEN one considers the great number of surgical treatises, text-books, and manuals which have appeared during the past few years, nearly all of which exhibit the evidences of careful preparation, it is difficult to understand why many able surgeons are willing to devote so much of their valuable time to an occupation which promises little return, for no one will for a moment maintain that all these additions to the literature of surgery are needed, because the field has already been covered many times by writers upon every variety of surgical subjects—producing works of all sizes and successfully meeting every condition and want of the specialist, general practitioner, and student.

The manual recently presented to the profession by Rose and Carless, however, possesses many features of unusual merit; and if one could have access to but a single volume on surgery, we know of no book of the same size which could be relied upon to furnish more accurate knowledge or common-sense advice upon most surgical subjects.

In the first six chapters, which are devoted to surgical pathology, one can find a clear and concise statement of the essentials. In the chapters on fractures and dislocations the authors have been able to condense into a hundred pages the salient points in the diagnosis and treatment of these conditions; and in general the advice given is highly to be commended. The same may be repeated in regard to the treatment of head injuries, abdominal diseases, and hernia. The authors have, however, lowered their standard in some of the chapters upon special subjects. This is noticeably the case in those which treat of the diseases of the bladder and prostate and upon gonorrhoea and syphilis, none of which reflect views which could by any stretch of the imagination be regarded as modern.

These chapters bear the evidence of such marked ignorance as to the essentials of genito-urinary surgery as to lead to the belief that they were the perfunctory work of some assistant, rather than an expression of the views of the gifted authors.

Die Untersuchung und Begutachtung bei traumatischen Erkrankungen des Nervensystems. Ein Leit-faden für Praktiker. Von Dr. PAUL SEUTSTER, Assistent an der Prof. Mendel'schen Klinik in Berlin. Mit einem Vorwort von Prof. Dr. E. MENDEL. Berlin: S. Karger, 1899. Pp. 196.

THE relationship between injury and disease or disability has become one of the most important questions connected with medicine. In Germany, by the passage of the *Unfallversicherungsgesetz*, or accident insurance law, the interests of workmen or employees injured in the pursuit of their occupation are provided for. This involves careful examination and observation of the injured person, and consequently an increased general at-

tention to diseases and conditions resulting from injury. In this country court calendars are largely filled with personal-injury suits. There are now several periodicals devoted exclusively to the relationship between disease and accidents; the traumatic origin of various diseases, but especially of those affecting the nervous system, is much more frequently the subject of scientific investigation than it used to be. Monographs, such as Oppenheim's *Traumatic Neuroses*, Pearce Bailey's *Accident and Injury*, and the one now before us, are constantly appearing. That American physicians would do well to avail themselves more freely of the many opportunities for information on these subjects will be acknowledged by any one who is familiar with the character of much of the so-called expert testimony which is offered when a nervous malady becomes the subject of litigation.

While Dr. Schuster writes especially for the physicians who are brought in contact with the German law, his book is none the less to be commended to all who desire to familiarize themselves with the best ways of considering cases of traumatic nervous disease. His scheme for the important points to be brought out in reference to personal and ancestral history, as well as for the examination of the patient, is excellent. The subject of simulation also is handled in a much more common-sense way than is often done. As a kind of appendix, the histories and decisions in a variety of personally observed cases are cited. While the book is in no sense a treatise on diseases of the nervous system, it is a valuable *vade mecum* to the physician who is confronted by the problems to which they frequently give rise.

An Atlas of Bacteriology: Containing One Hundred and Eleven Original Photomicrographs with Explanatory Text. By CHARLES SLATER, M. A., M. B., M. R. C. S. Eng., F. C. S., Lecturer on Bacteriology, St. George's Hospital Medical School; and EDMUND J. SPITTA, L. R. C. P. Lond., M. R. C. S. Eng., F. R. A. S., formerly Demonstrator of Anatomy, St. George's Hospital Medical School. London: The Scientific Press, Philadelphia; J. B. Lippincott Company, 1898. Pp. xiv+120. [Price, \$2.50.]

This volume is the first attempt to produce at a reasonable price a fairly complete series of photomicrographs of pathogenic bacteria. The undertaking is most commendable, and the authors are to be congratulated on the evident success of their efforts.

The subjects treated include micro-organisms in stained smears, surface colonies, tube cultures, and infected tissues. The photographs of bacteria in smears are remarkably accurate productions, most of them showing exquisite detail in morphology. The photographs of colonies and tube cultures are very artistic and instructive, the dark backgrounds serving to bring into strong relief some of the delicate and important biological peculiarities of many species.

The authors' statement, that in bacteriology illustration by photography is more unsatisfactory than in any other branch of pathology, is fully verified by their own comparative failure to photograph bacteria in tissues successfully. In this department the picture is far less instructive than well-executed drawings. The photographs of malarial parasites also show very little of the morphology of these organisms. The authors are in error in offering a half grown pigmented tertian parasite as a "signal ring" form.

The introductory chapter, on the technique of photo-

micrography, indicates that the authors are familiar with all the modern refinements of the art, although they use a comparatively weak lime light, which is probably inferior to the carbon electric arc, and they apparently find no advantage in placing oil on the condenser. Their success has seemingly depended upon the careful choice of screens and upon laborious focusing.

A Manual of Bacteriology. By HERBERT W. WILLIAMS, M. D., Professor of Pathology and Bacteriology, Medical Department, University of Buffalo. With Seventy-eight Illustrations. Philadelphia: P. Blakiston's Son & Co., 1899. Pp. x+10 to 263. [Price, \$1.50.]

WITH the considerable number of condensed textbooks on bacteriology now within reach of the medical student and practitioner, any new contribution to this class must embody some very distinctive features to attain more than a limited circulation. This volume covers all departments of the subject, and the space devoted to many topics of importance is necessarily very limited.

The facts presented are principally those of immediate use for the beginner in this study, and the compilation has apparently been prepared for and is well adapted to the wants of the author's students. Beyond this field the volume is probably not expected to go, as it embodies no new facts, and has no distinctive features that may recommend it over other works of double its size.

Formulaire des médicaments nouveaux pour 1899. Par H. BOCQUILLON-LIMOUSIN, Membre des sociétés de pharmacie et de thérapeutique, etc. Avec une introduction par HENRI HENRIARD, Membre de l'Académie de médecine. Paris: J.-B. Baillière et fils, 1899. Pp. viii+9 to 332.

MANY of our readers are no doubt familiar with this excellent little book, the admirable qualities of which we have described in notices of its earlier editions. That its language may militate against its full measure of usefulness with American readers is of course true, but medical French is not as a rule a difficult matter, and in the present instance becomes less an obstacle than usual because of the pithy and sententious style of composition that is employed. If one cares to be informed upon the "description," "pari used," "therapeutics," "method of employment," and "dose" of all of the most recent drugs, and that in small space and authoritatively, he should possess himself of this volume.

Human Anatomy: A Complete Systematic Treatise, including a Special Section on Surgical and Topographical Anatomy. By Various Authors. Edited by HENRY MOHR, M. A., M. B. Lond., Surgeon to the Middlesex Hospital, etc. Translated by Seven Hundred and Ninety Writers. The Greater Part of which are Original Authors. A Handy for this Work by Special Arrangement. One Hundred printed in Colors. Second Edition. Philadelphia: Enlarged. Philadelphia: P. B. Blakiston's Son & Co., 1898. Pp. xxix+1274. [Price, \$10.00.]

It is a pleasure to welcome a new edition of this valuable anatomy. It is a work of great merit and a time as a new work of the same kind.

As in the first edition, the work is divided into

with the minute anatomy of the body, only what can be actually seen by dissection being described. Still, it by no means is to be put in the category of the so-called dissectors, as considerable space is devoted to the ontogeny and phylogeny of structures.

The illustrations, which were a marked feature of the first edition, have been further added to and in some cases improved. Additional chapters have been inserted on the skin and on vestigial and abnormal structures.

The work is a composite one, but the various parts have been so thoroughly revised by the collaborators that it is quite homogeneous, and the high reputation of the individual writers speaks for the whole.

We had hoped that in this edition the description of anomalous muscles, instead of having a separate place, would be inserted in the general description of the muscles of which they were variations. Still, the course followed is a small fault and readily condoned.

It is exceedingly refreshing to read this anatomy. Its descriptions are lucid, terse, and, best of all, correct. It certainly deserves the high place it has won among the foremost of our anatomies.

A Manual of Physiology. With Practical Exercises. By G. N. STEWART, M. A., D. Sc., M. D., Edin., D. P. H. Camb., Professor of Physiology in the Western Reserve University, Cleveland, etc. With Numerous Illustrations, including Five Colored Plates. Third Edition. Philadelphia: W. B. Saunders, 1899. Pp. 5 to 848. [Price, \$3.75.]

AN enlargement of some fifty pages has been made in the text of Professor Stewart's book, and twenty-two new figures have been added. In bringing the work as nearly as possible up to the date of issue, however, much of the original matter has been condensed to make room for what is new. The additions are well chosen and valuable, including the results of all important researches published since the date of the first edition, 1895. Cannon's work, for example, on the movements of the stomach as studied with Röntgen rays, published in May, 1898, is reported fully.

And the ready conversion of the results of research into text-book form has not been confined to the text alone. The practical exercises, excellent in the first edition, have been still further developed. Experiments to demonstrate the influence of gravity upon circulation and the effect of the injection of albumoses and suprarenal extracts, and of hemorrhage and transfusion, upon blood pressure may be taken as fair examples of the additions.

Throughout the entire volume there is a perfect balancing of the theoretical with the practical. This and the general style of the book recommend it most strongly to medical students, though the research worker will find in it a concise, reliable, and recent treatment of nearly every field.

BOOKS, ETC., RECEIVED.

The Principles of Bacteriology. By Dr. Ferdinand Hueppe, Professor of Hygiene in the University of Prague. Authorized Translation from the German by Dr. J. O. Jordan, Assistant Professor of Bacteriology in the University of Chicago. Chicago: The Open Court Publishing Company, 1899. Pp. x+167. [Price, \$1.75.]

The Microscope of Drinking Water. By George Chandler Whipple, Biologist and Director of Mount

Prospect Laboratory, etc. First Edition. First Thousand. New York: John Wiley & Sons, 1899. Pp. xii+300.

Railway Surgery. A Handbook on the Management of Injuries. By Clinton B. Herrick, M. D., Attending Surgeon to the Troy Hospital and the House of the Good Shepherd, etc. Profusely illustrated by Numerous Original Engravings. New York: William Wood & Co., 1899. Pp. xii+265.

Vaccination: its Natural History and Pathology. Being the Milroy Lectures for 1898 delivered before the Royal College of Physicians of London. By S. Monckton Copeman, M. A., M. D., Cantab., M. R. C. P. Lond., Medical Inspector to her Majesty's Local Government Board, etc. London and New York: The Macmillan Company, 1899. Pp. x+257. [Price, \$2.]

The Dawn of Reason, or Mental Traits in the Lower Animals. By James Weir, Jr., M. D. New York and London: The Macmillan Company, 1899. Pp. xiii+234. [Price, \$1.25.]

Notes on Surgery for Nurses. By Joseph Bell, M. D., F. R. C. S. Edin., Consulting Surgeon to the Royal Infirmary and to the Royal Edinburgh Hospital for Sick Children. Fifth Edition, thoroughly revised. Edinburgh: Oliver & Boyd. London: Simpkin, Marshall, Hamilton, Kent, & Co., 1899. Pp. 9 to 194. [Price, 2s. 6d.]

New York Post-graduate Hospital. Fourteenth Annual Report of the Directors for the Year ending October 1, 1898.

Second Annual Report of the Forest Preserve Board of the State of New York for the Year 1898.

Reports of the Trustees and Superintendent of the Butler Hospital for the Insane. Presented to the Corporation at its Fifty-fifth Annual Meeting, January 25, 1899.

Clinical Report from the Winyah Sanitarium. Seventy-eight Cases of Pulmonary Tuberculosis Treated and Discharged in 1898. By Karl von Ruck, M. D., Director of the Institution, Asheville, North Carolina.

Positive Proofs that the Blood can Circulate without the Aid of the Heart. By Matthew Joseph Rodermund, M. D., of Appleton, Wisconsin. [Reprinted from the *Chicago Medical Times*.]

The Etiology and Diagnosis of Empyema of the Accessory Sinuses of the Nose. By Jacob E. Schadle, M. D., of St. Paul. [Reprinted from the *St. Paul Medical Journal*.]

The Physician in Practice. By Leo M. Crafts, M. D., of Minneapolis. [Reprinted from the *Journal of the American Medical Association*.]

Miscellany.

The Treatment of Pulmonary and Laryngeal Tuberculosis with Antiphthisic Serum T. R. Dr. W. Freudenthal (*Medical News*, February 18th), in a paper on this subject, records four cases of tuberculosis treated with the antiphthisic serum T. R. Dr. Freudenthal concludes his paper as follows: "Although these results are not so gratifying as those obtained by Dr. Carl Fisch

or by Dr. A. M. Holmes, of Denver, nor as unfavorable as those of Dr. F. E. Waxham, of Denver. I must say that I am of the opinion that this new serum is a remedy which should be tried much more extensively. When we have a series of hundreds of cases, carefully watched and recorded, we will be better able to pass judgment on its value. Until then all well-observed cases will help to form an opinion, and in furtherance of this object this report is published."

Behring vs. Calmette.—According to the *Journal of the Mississippi State Medical Association* for February, citing *Lancet*, November 5, 1898, and *Journal of the American Medical Association*, Dr. Calmette, Pasteur's well-known pupil, who was recently appointed as chief organizer of the Pasteur Institute at Lille, and who has won much fame by his researches into the question of immunity for serpent venom, has made another discovery of a more purely commercial nature. By this discovery he was enabled to manufacture alcohol very much purer and stronger than is usual at a distillery and at the same time much more cheaply. He sold his secret to a large factory near Lille and very soon realized the handsome sum of two hundred and fifty thousand francs. This he has handed over absolutely to the Pasteur Institute, over which he presides, although he is not personally a wealthy man. This act of munificence, which has been noticed solely by the medical press and ignored by the political journals, is considered as a protest against the recent action of Dr. Behring.

Ichthyol in Phlyctenular Disease of the Eye.—Dr. Wendell Reber (*St. Louis Medical Gazette*, February) concludes a paper on this subject as follows:

"1. That phlyctenulosis of the eye is nearly always of nasal or strumous origin; even when it is nasal it is rather to be viewed as the terminal expression of a constitutional vice.

"2. That phlyctenular affections of the eyes are peculiarly amenable to one- to two-per-cent. solutions of ichthyol when used jointly with hot stupes.

"3. That when the phlyctenular process has been cured, correct ordering of the daily life, regulation of diet, roborants and alteratives, and attention to the condition of the upper air-passages are all of equal importance from the standpoint of prevention, which is, after all, the only true goal. Should one of these phlyctenule develop near the centre of the cornea, the resulting scar would almost surely impair vision during the remainder of the patient's life; hence the importance of prophylaxis."

The Inflammability of Celluloid Hairpins to the Static Breeze.—According to the *Medical Register* for January 15th, the editor of the *Journal of Electro-therapeutics*, having had a most disagreeable experience, and what might have proved to be a serious accident, takes the opportunity of calling attention to the circumstance under which it occurred, that others may be on their guard for like contingencies. A young lady was being treated with the static breeze on the head through an ordinary static head-crown. The crown was about 10 or 12 inches from the hair, and was attached to a five or six feet pole of the battery direct, while the patient herself was in connection with the stool on which the battery sat. The day was clear, and the charge generated was moderately strong. But it was above the average of such treatments, it was only slightly so, and certainly not less than has often been given. The hat having been re-

moved, the shower came down in profusion over the head and shoulders, and was not at all disagreeable until suddenly a scream and the most painful expression of countenance gave warning that something had gone wrong. The motor was at once disconnected. A column of smoke arose from the patient's head while she continued to scream the louder. Before the narrator could reach her a second column of smoke, and then a third arose. He tore down the hair with all possible haste, and removed the charred remains of three celluloid hairpins, one of which was only partially destroyed. He succeeded in smothering the fire with his hands only after three spots of hair had been burned away, varying in size from a quarter to a half dollar.

The Diagnosis of Functional Heart Murmurs.—Dr. Maude E. Abbott (*Montreal Medical Journal*, January) concludes a paper on this subject as follows:

"The cases studied illustrate especially the following points: 1. In cases of anæmia, pulmonary accentuation is often associated with a pure accidental murmur. 2. Functional murmurs frequently occur when there is neither anæmia nor fever. They are then often associated with some other condition suggesting intoxication. 3. Diastolic murmurs have been noted which do not appear to have an organic origin. 4. Although accidental murmurs are generally heard at the base and those of relative mitral insufficiency at the apex, accidental murmurs are probably sometimes heard at the apex (as in moderate anæmias, where the murmur may occur at the apex unaccompanied by pulmonary accentuation or cardiac enlargement and disappear after a short time; or in high fevers, where a murmur at the apex is replaced after a few days by one at the pulmonary cartilage of the same character). On the other hand, murmurs produced at the mitral valve are occasionally, though rarely, heard best at the pulmonary cartilage.

"Two conditions which it may be quite impossible to distinguish from each other by physical signs are: A functional murmur at the apex with signs of moderate dilatation (relative mitral insufficiency), and an organic mitral murmur with signs of compensatory change. A decision can often only be reached by considering the patient's general condition and the persistency of the murmur. This last is the clinching point and is the final criterion to which uncertain cases must be brought. In plain terms, we must wait to diagnose the murmur until it is no longer there to diagnose."

Malarin, a New Antipyretic.—According to the *British Medical Journal* for January 21st, citing the *Therapeutische Monatshefte*, No. 10, 1898, a new antipyretic has been prepared by Valentiner and Schwarz. Malarin is a yellowish white powder, insoluble in cold water, but causes the powder to dissolve, and it does not cause any cooling. If the water is neutral or weakly acid, the addition of sodium malarin powder is freely absorbed. The physiological characteristics have been examined by Schwarz. He found that malarin was not a narcotic. A dog weighing four kilograms was given 0.5 gramme of malarin daily for five days, and showed no signs of intoxication. Schwarz also found that two grammes without any ill effect. The antipyretic action of malarin has been tested by giving it to a dog with a temperature of 40.5°C. The effect was a rapid reduction of malarin to 38.5°C. The antipyretic action of malarin also lowered the temperature of a dog with a temperature of 40.5°C. The antipyretic effect was produced by the malarin, and not by the water. In these cases only the malarin was given, and the water

of temperature, which end fatally. Malarin in these cases has a powerful effect in diminishing the convulsions, and in several instances actually stopped them, even when a fatal dose of the poison had been given. The convulsions produced by picrotoxine are not influenced by malarin. No clinical records have yet been made of the action of this drug, but, according to Schwarz, it may be used as an antipyretic and antispasmodic.

An Alcohol Dressing for the Umbilical Cord.—Herr Budberg (*Centralblatt für Gynäkologie*, 1898, No. 47, p. 1288; *Presse médicale*, January 11th) has employed an alcohol dressing for the umbilical cord in about two hundred cases. The alcohol possesses antiseptic properties, and is said to dissolve the fatty material and dry the tissues. After the infant has been bathed, the umbilical cord is dried and surrounded with absorbent cotton soaked in alcohol. Over this is placed a second dressing of absorbent cotton. The usual binder is then applied. This dressing is changed once or twice a day till the cord falls off. During this period it is best not to bathe the child. Either absolute or dilute alcohol may be used. No pain or irritation seems to follow the dressing.

Transverse Wound of the Wrist; Division of Extensor Communis Tendons; Suture of Cut Tendons to Tendon of Extensor Indicis.—Dr. Delamare (*Archives de médecine et de pharmacie militaires*, 1898; *Post-graduate*, January) reports the case of a soldier who was struck just below the wrist by a piece of glass, completely severing the tendon of the extensor communis digitorum, which ran to the middle, ring, and little fingers. Some days afterward an attempt was made to suture the tendon, but only the peripheral ends could be found. These three ends, therefore, were joined and sutured to the uninjured tendon of the same muscle running to the forefinger. As the tendon alone could not be trusted to furnish sufficient strength and firmness, the entire bundle of tendons of the extensor communis was sutured also to the tendon of the extensor indicis. Healing occurred by first intention. The functional result was admirable—the patient being able to move the fingers perfectly.

Rare Symptoms of Iodism.—According to the *Lancet* for January 21st, M. Danlos, at a recent meeting of the *Société médicale des hôpitaux*, described some rare symptoms produced by iodide of potassium. A man, aged sixty years, took seven grains and a half of iodide of potassium on one day and fifteen grains on the next, when he had slight signs of iodism—coryza and disagreeable taste in the mouth. There was considerable suprahoid tumefaction, symmetrical and not extending to the parotid region. There was no spontaneous pain and but little tenderness, and the color of the skin was not altered. The saliva was not affected. Palpation showed no ardor but an elastic swelling in which the submaxillary glands were felt to be swollen and a little tender. The iodide was supposed to be the cause and was stopped. Three days later the swelling had disappeared. To complete the proof a similar result was produced twice on administering the drug. Elimination of iodine was rather slow; two hours after administration there was scarcely a trace in the urine and it was found abundant on the following day. The only allusion to the subject which M. Danlos could find in literature was the statement of M. Lounier that in the treatment of syphilis, when the salivary gland, principally of

the parotid gland, had been noticed. Another case was related. An old patient of the Saint Louis Hospital who had suffered from syphilis was given daily forty-five grains of iodide of potassium. After ten days he complained of violent itching and an erythematous and bullous eruption developed. The iodide was stopped, but the eruption continued to appear, and twelve days later the itching was excessive, preventing sleep. There was a discrete bullous eruption on the back of the hands, feet, face, and ears. On the trunk and arms there were numerous erythematous patches and urticarial wheals both on and apart from the latter. The eruption declined under arsenate of sodium, but only after ten days' administration. A point of interest was that the eruption continued to appear for more than six weeks after the discontinuance of the iodide of potassium. Also the eruption was a typical dermatitis herpetiformis as described by M. Brocq—a form of eruption not previously observed as a result of iodism.

Orchitis as the First Symptom of Urinary Infection following Stricture.—M. Carlier (*Gazette hebdomadaire de médecine et de chirurgie*, January 26th) reported recently to the French Association of Urology two cases of old-standing blennorrhagia in which no troubles of micturition existed, or at least none such as to lead the patients to consult a physician, but in whom an attack of painful and swollen testicle with fever compelled them to do so. This appeared to be the first noticeable symptom of stricture. Internal urethrotomy promptly put matters right.

A Premonitory Symptom of Chloroform Poisoning.—Lehmann (*Journal de médecine de Paris; Revue médicale*, February 1st) has made observations on three hundred and twenty-nine cases of anæsthesia, in twenty-one of which was observed the fact that the patient kept the eyes partially or completely open, and reopened them on their being closed, and in each of these twenty-one cases various accidents supervened—*e. g.*, repeated vomiting (notwithstanding an empty stomach), sudden stoppage of respiration, a prolonged stage of excitement, and even symptoms of asphyxia and syncope calling for persistent artificial respiration. From these observations he concludes that this symptom should be regarded as a premonitory sign of more or less serious complications.

The Difficulties of the Practitioner of Medicine.—Dr. H. A. Tomlinson (*St. Paul Medical Journal*, February), in an article on The Personal Equation in Medical Practice, thus aptly describes some of the difficulties that beset the practitioner of medicine:

"The practice of medicine is singular in that it almost necessarily isolates its devotee from his fellows, and peculiar in that it depends upon a kind of knowledge which is not common and bears no relation to the ordinary affairs of men. Neither are the causes of success or failure to be estimated by any general standard. The most trifling case of illness, even, presents so wide a divergence between the abstract entity involved in the perverted physiological process and the illness as a whole, conditioned by all that enters into the environment of the individual who is ill, that to estimate the one by the other is impossible; as it is futile to attempt to determine by the history of an illness in one case exactly why another apparently similar should have run so different a course. More than in any other profession the physician is separated from his fellow workers. He has to meet the exigencies of ordinary practice alone, and often the

most extraordinary difficulties have to be encountered without the aid of any one. Again, his relation to those whom he is called upon to treat is peculiar and difficult. Conscious of the absence of certainty in the methods of diagnosis and treatment of disease, and the number of factors which, although their existence can seldom be definitely predicated, may enter into the aetiology or modify the course of disease in any individual, yet he must always, for his patient's sake, and to retain the confidence of the family, appear absolutely certain of his ground; precise and sure of the wisdom of every step taken. There is before him all the time the knowledge of the different standpoint from which the layman, through the influence of superstition and credulity, looks upon medical practice; so that he can not appeal to his patient's judgment to help him out, because the uncertainty on his part, born of knowledge of the limitations of medicine, appears, and is almost sure to be considered by his patient as evidence of ignorance and incompetence. He finally grows into a mental habit more or less narrow, according to his original bent and the breadth of his training; so that his judgment is practically uninfluenced by anything outside of the experiences which condition his own environment. His conclusions meet the test supplied by the exigencies of his practice. His patients get well as a rule, and when they do not he recognizes that after all human intelligence is limited and disease is sometimes bound to be fatal. Then, too, if the physician has been successful to more than the ordinary degree, he is bound to become somewhat autocratic, to resent any questioning of his authority or difference of opinion. So that while he may seek eagerly the enlightenment which comes from the written records of experience at a distance, he has little or no confidence in that of his fellows when they reach different conclusions from the same premises. He comes to wonder how such men ever attain any success in practice, and while he pities those who are under the care of such poorly equipped physicians, he comforts himself with the knowledge that the tendency of all acute disease is toward recovery. It is so easy for us to recognize the skilled physician in the man whose methods are the same as our own, and so difficult to see any evidence of trained knowledge in those who differ from us."

The Significance of the Pulse in Tuberculosis.—According to M. Durand (*Revue médicale*, February 8th), the examination of the pulse in tuberculosis is of the utmost importance. The condition is serious if the pulse rate is maintained above 100, desperate if it exceeds 120 for several days. Consequently, he says, the examination of the pulse permits us to recognize curable forms of tuberculosis, or at least those of slow progress.

Uterine Displacements.—Dr. W. J. Gow, physician accoucheur to out-patients at St. Mary's Hospital, London (*Indian Medical Record*, January 11th), concludes an introductory address, read before the Medical Society, as follows:

"1. Backward displacement of the uterus is a factor to be observed, not a disease to be diagnosed. 2. There are several kinds of backward displacement. 3. In only one form will a vaginal pessary maintain the uterus in an inverted position. 4. Angular retroflexion is not affected by the introduction of a vaginal pessary, and if, therefore, you are not inclined to use an intra-uterine stem, or perform vaginodilation or ventrofixation, the retroflexion remains unaltered by treatment.

5. A bend in the uterus somewhere about the junction of the body and supravaginal cervix is natural. Are we therefore to believe that a bend in a backward direction is fraught with such dire results as some would have us believe?"

Hyperpyrexia in Rheumatism.—Dr. H. G. Langwill (*Scottish Medical and Surgical Journal*, February) thus sums up an exhaustive and interesting paper on the Treatment of Hyperpyrexia in Rheumatism:

"Briefly, then, I would venture to suggest the following as a summary of the chief points in reference to the prophylaxis of rheumatic hyperpyrexia: 1. Cases in which the pyrexia shows a tendency to rise instead of decline under full doses of the salicyl compounds, and in which no intercurrent condition can be detected which might account for the increasing pyrexia, should be treated at once by cold applications without waiting for the onset of nervous symptoms or other prodromata of rheumatic hyperpyrexia. 2. When delirium appears in a case which exhibits pyrexia, and no intercurrent visceral complication can be made out which might account for its presence, the immediate employment of cold is called for. 3. Should delirium appear while the temperature remains normal, a mild form of cold application—*e. g.*, an ice-cap to the head—should be employed, and on the appearance of pyrexia more vigorous methods ought to be adopted without waiting for any extreme degree of pyrexia (*e. g.*, 105°) to be reached. 4. Cases in which the hyperpyrexia is, as it were, accidentally discovered to be present offer, of course, no field whatever for prophylaxis, but treatment by cold should be commenced at once without waiting for the appearance of nervous symptoms or attempting to reduce the temperature by means of any antipyretic drugs."

Finally, he says:

"The main conclusions I would draw from the consideration of the whole subject of hyperpyrexia in rheumatism are these: 1. That the condition is more prone to occur in the warmer months of the year, and apparently with greater frequency in certain years. 2. That while it is very difficult to estimate at all accurately the frequency of its occurrence, probably this is about 0.5 per cent. among adult cases of rheumatism. 3. That the occurrence of hyperpyrexia in rheumatism is practically confined to cases of this disease in persons over fourteen years of age. 4. That the rare instances of hyperpyrexia which occur under that age are in cases of rheumatism which present the adult type of the disease. 5. That the absence of hyperpyrexia from rheumatism in children is probably to be explained as the result of the type rheumatism assumes in them rather than a mere question of the age of the sufferer. 6. That males show a much greater proclivity to the condition than females, which may possibly be associated with the greater strain habitually put upon their thermotaxic mechanism. 7. That the condition is most apt to occur in 'first attacks' of rheumatism. 8. That persons who have once suffered from the condition would probably be apt to have a recurrence of it in any subsequent attack of the disease (although no case of such recurrence has previously been published). 9. That it may occur at any stage in an attack of rheumatism, but probably the second week is the most common period of its occurrence. 10. That it may arise in even mild cases of rheumatism, severe rheumatic symptoms being necessary for its occurrence. 11. That the onset of hyperpyrexia is always gradual, without warning, has usually a maximum duration of the

chief of which is delirium. 12. That cases of true rheumatism showing persistence of the pyrexia, in spite of full doses of the salicyl compounds, should be most carefully watched, since hyperpyrexia frequently ensues in such instances. 13. That sudden cessation of the articular pains without coincident fall of temperature should lead to the suspicion of hyperpyrexia, especially if attended also by the cessation of sweating. 14. That MacLagan's hypothesis that hyperpyrexia is due to paresis of the heat-inhibiting mechanism from exhaustion in its attempt to control the excessive heat production of rheumatism, is the most feasible theory yet put forward in explanation of the condition, satisfactorily accounting for the more frequent occurrence of hyperpyrexia in adults than in children. 15. That the absence of rheumatic hyperpyrexia in children is a strong argument against the view that this condition is due to visceral complications, since it is especially in children that these visceral manifestations occur, and it is just in those cases that hyperpyrexia is not found. 16. That in view of the resemblance in several respects between rheumatic hyperpyrexia and 'diabetic coma,' further investigation of this subject might possibly throw fresh light upon the pathogenesis of both conditions. 17. That while the mortality of rheumatism is only about three per cent., hyperpyrexia is probably one of the most important immediate causes of death in this disease. 18. That the mortality of hyperpyretic cases is very high, probably over fifty per cent., but statistics are very variable because—19. The mortality is greater the higher the temperature before treatment is begun; and 20. It is also greater among cases treated by means of antipyretic drugs alone. 21. That treatment by the application of cold in one of its various forms is the only justifiable method in cases of hyperpyrexia in rheumatism. 22. That this should be adopted even in cases apparently moribund, and even although visceral complications may be present. 23. That while there may possibly be some risk of congestion of internal organs as a result of this method of treatment, this does not justify the neglect of what is practically the only remedy for an otherwise fatal condition. 24. That the greatest care should be taken to prevent collapse ensuing in the patient as a result of the treatment by cold, which should be stopped entirely before the treatment falls to normal. 25. That antipyretic drugs, while practically useless in the treatment of hyperpyrexia when present, may perhaps be of some service in preventing a recurrence of this after the temperature has once been reduced by means of cold. 26. That in obstinate cases of recurrent hyperpyrexia the method of treatment by 'disintoxication of the blood' adopted by Barré may probably be of service as an adjunct to the treatment by means of cold. 27. That a greater attention should be paid to the prophylaxis of rheumatic hyperpyrexia, and that more prominence should be given to the advantage of commencing treatment by cold at an early stage before excessive temperatures are attained; in other words, the general condition of the patient, rather than the mere height of his temperature, should be the determining factor for commencing the treatment by cold. 28. That early and complete subjection of the patient to antirheumatic treatment would probably have some influence in preventing the occurrence of hyperpyrexia."

The Bearing of Obesity on Health. Dr G. A. Heron (*Medical Examiner*, February), in a paper on *Some Extra Ratings of Healthy Lives*, read before the Life Assur-

ance Medical Officers' Association, London, speaking of the risk of obesity, says:

"Many stout people are healthy; but some stout people fall into obesity. Although I have searched for it, I have hitherto failed to find a good definition of the physical conditions which stamp a seemingly healthy man as too fat for health. There is, however, a well-known type of man of whom we may say, with much confidence, he will become unhealthily stout. Such men are, in early adult life, noticeable for their large, well-developed bones and muscles. They are full of the joy of living, and keenly alive to pleasures of the senses. Their appetites are large, and their powers of digestion excellent. But when we examine a person of this type, and find him healthy, and, but for the fact that he is increasing in weight and is too heavy for his height and age, would pass him as a first-class life, we should then inquire very carefully about such a man's family history; for it is certain obesity 'runs in families,' as the phrase goes. It is also certain that persons of this type, with an hereditary tendency to obesity, are much less frequently cured of their fatness than are people like in build to them, but without a family history of obesity. Now these sufferers from too redundant fat have for centuries been recognized by medical authorities, and other observant people, as being peculiarly unfitted to resist onsets of acute diseases, as being apt to be short-lived, and as being liable to sudden death. They are likely to die of those degenerations of arteries, muscles, and internal organs which we know are dangers threatening the life of the fat man. Men of this type, and with a family history of obesity, are prone to be too stout in infancy, and up to the time of puberty. If this additional fact can be elicited concerning a proposer of this kind, it ought to make us insist strongly upon an extra rating. But here, again, we have no reliable statistics to guide us in coming to a decision as to the amount of extra rating necessary. Therefore, each medical officer must do as he thinks right. For my own part, had I to deal with a proposer who seemed healthy, but was too heavy for his height and age, whose weight was increasing, who had been too stout between infancy and near to the time of puberty, and who had a family history of obesity, I should advise, for assurance purposes, an addition of fifteen years to the seemingly healthy man's age, or the equivalent of this in the shape of an endowment policy."

"Now, as to the man who has no family history of obesity, and who in early boyhood was not too stout. He may look the very picture of redundant health, a big, powerful man, bristling of energy. The only flaw is, he is too heavy, and his weight is increasing. We know this flaw in such a man is the expression of a threatened departure from health; and it is, almost always, curable in those who have no family history of obesity, and who will submit themselves to necessary treatment in early adult life, when the first threatening of coming obesity usually shows itself. It does not seem fair that this man should be rated on the same scale as the other type of stout man, just now mentioned. The former is clearly a much better life than the latter, and should, I think, have the offer of an endowment policy payable at the age of sixty years. For the reasons mentioned I venture to advise the use of the endowment plan, until we have a reliable statistical table for the regulation of extra ratings in these cases."

"When women are threatened with obesity they should, I think, be rated as men are."

"The too fat man who wishes to assure his life to the best advantage to himself should select for his purpose an office of good standing which has stout men among its directors."

Fœtus in the Abdomen of a Man.—The *Western Druggist* for February says that a peculiar case of heterogeneous fetation has been reported to the Paris Academy of Medicine: A young man was operated upon for what was supposed to be a large abdominal tumor. It proved, however, to be a dermoid cyst, containing a female fœtus as large as is usual at five months. The ovum in the cyst had probably lain latent until puberty or some traumatism had started it to grow. The young man did not long survive the operation, and died ignorant of the existence of a little sister in his supposed tumor.

Aneson, a New Anæsthetic.—According to the *Western Druggist* for February, Sternberg reports in the *Klinisch-therapeutische Wochenschrift* on a new anæsthetic named aneson, which he considers a useful and safe substitute for cocaine. It is a colorless, aqueous solution of trichlor-pseudo-butyl-alcohol, or acetone-chloroform, and corresponds to a 2 to 2.5 per cent. solution of cocaine, but has none of the latter's local irritation and is nontoxic. As much as seventeen grammes have been used without after-effects. The anæsthetic effect is also immediate, with no interval, as with cocaine. In suturing, a small amount of aneson injected at the points where the stitches are to be taken will prevent pain. Even inflammatory phlegmonous processes can be rendered perfectly insensible if sufficient aneson is used to keep them flooded all the time.

Zinc Sulphate in Chronic Gastric Catarrh.—According to Mercè's *Archives* for February, Caporali (*Journal of the American Medical Association*, January 21st) has treated certain cases of chronic gastric catarrh attended by an excessive flow of mucus by irrigating with weak solutions of zinc sulphate. Four cases are mentioned wherein the results were highly satisfactory. These patients had suffered for more than a year (in one instance four years) with epigastric pain, anorexia, eructations, and vomiting. The fluid withdrawn from their stomachs after a test meal contained little or no free hydrochloric acid or organic acids, but was loaded with glairy mucus. At first a solution containing one and a half to three grains of zinc sulphate to a quart of water was used, then with each washing out the proportion of this salt was augmented by three quarters of a grain, arriving finally at a dose of from eight and a half to twelve grains to the quart. Lavage was carried out with the stomach completely empty, and was immediately followed by irrigation with a two- or three-per-cent. solution of sodium bicarbonate, the object being to convert any slight quantity of zinc sulphate remaining in the stomach into zinc carbonate—an innocuous substance. Lavage with zinc sulphate conducted in this manner every day or on alternate days was always well borne by the patient and exercised a really curative action on the gastric catarrh, as manifested by a rapid diminution, and finally the disappearance, of all morbid symptoms and progressive increase in the patient's weight. The cure was maintained.

The Responsibility for the Care of Illegitimate Children.—The *Cincinnati Lancet-Clinic* for February 18th, quoting the *St. Paul Medical Journal*, says that a step

in the right direction has been taken in Germany that might be adopted with advantage in this country. Under a recent enactment, which goes into effect in 1900, the person or persons who have cohabited with the mother of an illegitimate child are made responsible for its support, and required to pay a certain sum annually for its maintenance, until the age of fourteen years. The time of cohabitation is fixed between the one hundred and eighty-second and the three hundred and second day. This law has no reference to the vexed question as to who is the father of the child, but casts the burden very properly upon all those who may have been proved to have had intercourse with the woman within the normal period of gestation. If there be more than one, the burden is divided between them. The mother retains possession of the child, which, however, may be adopted by the man if he so desires, without the obligation of marrying the mother. Such legislation is of evident value in throwing the responsibility of support where it belongs, and of destroying the most active incentive to infanticide.

The "Independent Medical College of Chicago."

In our issue for December 31, 1898, we quoted a paragraph from the *Indian Medical Record* for November concerning the Independent Medical College of Chicago, and expressed our curiosity to know what this institution was. The *Western Druggist* for February gratifies our curiosity, and we reproduce its description for the benefit of our readers. The *Western Druggist* says:

"For the enlightenment of our esteemed contemporaries it may be stated that the Independent Medical College of Chicago is a 'fake' pure and simple, not worthy even of being designated a 'diploma mill,' for it has no 'mill' attachment to give it the suggestion of an appearance of a teaching institution. This affair is a disgrace to the city of Chicago and State of Illinois which the authorities have striven in vain for several years to suppress.

"The persons principally interested in this 'college' are James Armstrong and Charles M. Hovey, and their address is corner of W. Vanburen and S. Leavitt Streets. They have neither school room, nor classes, nor lecturers. Any one, on the payment of a sum agreed upon—ranging from twenty-five to fifty dollars—can receive a doctor's diploma upon answering a few innocent questions put by the 'dean' to 'satisfy' him as to the 'competency' of the candidate; the same valuable (to the peddler's) diploma is also granted, 'soberly' on the applicant's filing in and paying a question of blank, the 'faculty' judging of the correctness of these answers. Formerly these fellows, known locally as the 'Armstrong crowd,' conducted their nefarious business under the title of 'The Illinois Health University,' doing a flourishing business all over the country. For some years of health, after some difficulty, succeeded in procuring a charter, which was regular enough, except that immediately thereafter these same men, now called under the new name of the Independent Medical College, and continued business at the old stand, the institution again being threatened by the law. Armstrong and Company have now obtained a 'National International University,' and under the present State charter law there is nothing to prevent them from selling the license. Then the old game of hide-and-seek will begin all over again."

The Death of Sir John Struthers, M. D.—The death is reported from London of Sir John Struthers, vice-

president of the Royal College of Surgeons of Edinburgh. The deceased physician was born in 1823. At the time of his death he was examiner in anatomy at the Royal College of Surgeons of Edinburgh. He had also held the appointments of lecturer on anatomy at the University of Edinburgh, surgeon to the Edinburgh Royal Infirmary, professor of anatomy at the University of Aberdeen, and was, moreover, a member of the British General Medical Council. He was the author of several anatomical works.

The Physician's Code of Ethics not Narrow or Antiquated.—This was the title of the inaugural address of the president of the New York County Medical Association, Dr. Frederick Holme Wiggin, delivered February 20th, at the Mott Memorial Hall.

Dr. Wiggin said he embraced the opportunity to enlighten both physicians and the laity more fully regarding certain portions of the national code of medical ethics about which there seemed to be much misapprehension. He began by disavowing the slightest intention of stirring up old strifes, and stated that he had selected this special topic solely because, in his intercourse, not only with his professional brethren but with various men of affairs, he had been impressed with the fact that certain very important parts of this subject were quite generally misunderstood. For instance, only a few months ago a high official in the Homœopathic Medical Society of the State of New York had told him that when the American Medical Association and its affiliated societies were ready to open their doors to those who held different views from those of the majority as to the action and doses of drugs, he, for one, would be willing to leave his organization, discard his sectarian title, and apply for membership. This gentleman, like many others, was not aware that years ago the American Medical Association had taken this very position.

In spite of all that had been said since regarding the code of medical ethics, the members of the medical profession in this country had lived under it in reasonable harmony from the organization of the American Medical Association in 1848 until 1882. In the latter year the first note of discord had been struck by the Medical Society of the State of New York, which, at its annual meeting in Albany, had adopted a different code. As this was in direct violation of one of the by-laws of the national organization, the judicial council of the latter society, by a unanimous vote, excluded the New York delegation. As a result, the members of the profession residing in this State who still desired representation in the national body were constrained to organize the New York State Medical Association and the New York County Medical Association. This division of the profession, with its resulting dissensions, was especially unfortunate because it arose from a misunderstanding, and was, therefore, wholly unnecessary. The American Medical Association had endeavored to clear up any doubt upon the main question at issue, that of consultations with homœopathic practitioners, by adopting in May, 1881, a series of resolutions making clear the fact that the national code contained no provision in any wise inconsistent with the broadest dictates of humanity and the exercise of the most perfect liberty of individual opinion and practice, and that the true ground for declining professional fellowship with any class of practitioner was not their belief in any particular doctrine, but their adoption of sectarian names as trade marks, and the formation of organizations antagonistic to the great mass of the medical profession.

This action of the national body, Dr. Wiggin said, had certainly opened the door years ago for the return to the parent organization of the members of the New York State and county societies, and that the members of the county society now appreciated this fact, and occupied identically the same position, was evident from the inaugural address, in 1897, of its president, Dr. Arthur M. Jacobus, who, in speaking of certain sectarian practitioners, said: "If they will but drop the sectarian title for that of physician, pure and simple, and let the old and new school questions die out, I am sure we will welcome them with open arms."

In closing his address, Dr. Wiggin said that, although the local profession might be compelled to wander a few years longer in the desert of disorganization, it was fair to predict that early in the twentieth century a Moses would be found who would lead the profession into the promised land of union and strength. When that glad time should arrive when all educated physicians in this State would join hands, he hoped the larger and reorganized society would adopt as its motto a paraphrase of that of the famous Musketeers of Dumas: "The profession for the individual practitioner, and the individual practitioner for the profession."

A Fire in a Philadelphia Drug House.—A very destructive fire recently broke out in the establishment of Messrs. William R. Warner & Co., compelling the firm to fill orders from their laboratory for the time being.

The German Medical Society of the City of New York will hold its next meeting on Monday evening, March 6th, at 8.15 o'clock. Dr. J. Guttman is to read a paper on *The Use of Holocaine as a Local Anæsthetic in Operations on the Eye, Ear, Nose, and Throat* (to be discussed by Dr. H. Knapp, Dr. J. W. Gleitsmann, Dr. M. Toeplitz, Dr. W. Freundthal, and others); and Dr. Joseph Fränkel is to read a paper on *Syphilis and Facial Paralysis*.

The New York Academy of Medicine.—At a stated meeting, on Thursday evening, the 2d inst., a discussion on syphilis was opened, during which the following papers were presented: *The Treatment of Syphilis in its Early Stages*, by Dr. R. W. Taylor and Dr. L. Bolton Bangs; *The Differential Diagnosis of Syphilitic Eruptions and Signs in the Skin of Former Syphilis*, by Dr. George H. Fox; and *The Stigmata of Syphilis in Children*, by Dr. R. H. M. Pawbarn.

At a special meeting, to be held on Thursday evening, the 9th inst., the following papers will be presented: *Syphilitic Affections of the Heart and Lungs*, by Dr. Leonard Weber; *Syphilitic Affections of the Liver in Adults and in Children*, by Dr. J. George Adami, of Montreal; *Visceral Syphilis in Children*, by Dr. A. Jacobi; *Syphilis in Relation to Obstetrics*, by Dr. Egbert H. Grandin.

At a stated meeting, to be held on Thursday evening, the 16th inst., the following papers will be read: *Some Surgical Aspects of Syphilis*, by Dr. Frank Hartley; *Syphilitic Dementia and Paretic Dementia, and the Treatment of Syphilis of the Nervous System*, by Dr. C. K. Mills, of Philadelphia; *Syphilitic Affections of the Spinal Cord*, by Dr. B. Sachs; *The Ophthalmological Aspects of Syphilis*, by Dr. C. S. Bull; and *Syphilitic Affections of the Respiratory Passages*, by Dr. Francke H. Bosworth.

A STUDY OF THE NATURAL HISTORY
OF THE CLINICAL MANIFESTATIONS AND
PATHOLOGICAL CHANGES IN
DISEASE OF THE LUNGS AMONG THE INSANE.

By H. A. TOMLINSON, M. D.,

SUPERINTENDENT ST. PETER STATE HOSPITAL, ST. PETER, MINN.

IN the *International Medical Journal* for March, 1895, I published a paper giving the results obtained from the study of the degenerative and destructive diseases of the lungs among the insane in this hospital. Since that time the study has been continued with even more care and elaboration, and special attention has been given to the clinical manifestations and natural history of the pathological changes which mark the course of these degenerative and destructive processes. As a result of this more careful study, we have found that these changes are not confined to those cases in which the apparent cause of death has been phthisis, but that sometimes quite marked destructive change has been going on in the parenchyma of the lung in cases showing a very different clinical picture, in which the immediate cause of death has been some other organic or general disease.

Since January, 1895, there have been a hundred and sixty-seven deaths, of which fifty have been recorded as due to phthisis in some of its forms. Out of this number a necropsy has been made in seventy-two cases, and of this number studied post mortem twenty-four were cases of phthisis, while the rest represented different forms of organic and general disease. However, in none of the cases studied was there complete freedom from lung involvement, while in some of the cases in which death was due to nephritis the progress of degeneration was as great as in the well-defined case of pulmonary tu-

tuberculosis. During the year 1895 and a part of 1896 we had very little tuberculosis in the hospital; but in the fall of 1896 there was a marked increase in the number of cases, and the illness of our herdsman from acute tuberculous infection, as well as the death of a patient from tuberculosis who was one of those working in the cow barn, led to the examination of our herd, with the result of finding half of the herd infected with tuberculosis.

The increase in the number of deaths from this cause went on until the warm weather enabled us to get our patients out of doors, in spite of the fact that all the milk from the infected and suspicious cows was boiled before using and the unsound cattle isolated. Another cause for the increase of tuberculous infection during the past two years has been the great overcrowding of the institution. This, in connection with the fact that the buildings are old, ill ventilated, and poorly constructed from a sanitary standpoint, has made infection much more common than it would be in a new or better constructed set of buildings. During the time covered by this study we have not had a single case of tuberculosis at the time of admission to the hospital, all of the patients being either primary degenerates, a year or more in residence, or else terminal demented who had been in the hospital a number of years. The nationality of those dying of phthisis was distributed as follows: Scandinavian, seventeen; Irish, thirteen; German, ten; American, seven; French, two; Polish, one. So far as could be found out, none of the patients dying of phthisis during this period had a heredity of tuberculous disease, although there may have been a collateral or preparental history, as our hospital population is largely made up of people who have been in America during one generation only.

Since January 1, 1895, seventy-two post-mortem examinations have been made, and in the following table will be found the cause of death and the condition of the lungs in these cases. I wish also to note here that in

Morbid Anatomy of Lung Tissue.

Cause of death in seventy-two cases coming to post-mortem examination from January 1, 1905, to June 1, 1905	No. of cases	One lung	Both lungs	In case of Strunk, don't count in both	Strunk without emphysema	Strunk with emphysema	Notifiable with emphysema	Notifiable without emphysema	Total with emphysema	Total without emphysema	Total
Cerebral tumor	1		1			1					1
Cerebral embolus	2		2			1					1
Cerebral syphilis	1		1	1							1
Cerebral hemorrhage	1		1			1					1

Chronic nephritis	22	1	21	10	5	2	5	5		5	10
General atrophy	1		1	1							1

all of these cases a proportionate degenerative change had taken place in the other vegetative organs and the brain, being most marked in the kidneys; the spleen and the liver following in the order named.

From the fact that none of these cases were recent, it will be seen that the degenerative process must have been ingrafted upon some preexisting condition rendering the pulmonary tissue susceptible to infection by the tubercle bacillus and the pus-forming bacteria. It will also be noted that destruction of lung tissue was almost as frequent in those dying from renal inadequacy as in the cases in which the progressive asphyxia due to respiratory failure was the cause, and that in all the cases examined post mortem some degree of degenerative change had taken place in the lung tissue; although at no time were the physical signs conspicuous enough to attract attention from the other diseased conditions present, while, so far as we could determine from the clinical progress of the cases, the destructive change in the lungs became apparent only after the vitality of the patient had been materially reduced by preexisting general disease or organic change in some other form. Again, even in those cases in which there was no destruction of lung tissue, there was marked increase in the density of the lung, which under the microscope proved to be the result of connective-tissue hyperplasia, and this increased density was always in proportion to a similar degenerative change going on in the other vegetative organs.

In all the cases there were pleural adhesions, varying from slight bands at the apex to complete obliteration of the pleural cavities. The greatest amount of adhesion existed in the chronic tuberculous patients and the least in those dying from general paralysis. In the case of mammary carcinoma one lung was entirely destroyed, while in the case of sarcomatosis both lungs were densely fibroid, with sarcomatous nodules throughout the lungs. The increased density in the lung tissue was most marked in those patients who exhibited the gross stigmata of degeneracy and whose mental condition was the result of defective development, and in these cases the nature of the degenerative change in the lung was further exemplified by the presence of similar changes in the liver, spleen, and kidneys. Furthermore, the character of the degeneration was in constant relation with the degree of defect in the nervous organization of the individual and the amount of degenerative change in the brain.

A singular episode in the clinical history of tuberculous infection among the insane has been the occurrence of a certain number of cases among primary degenerates of an acute illness, with high temperature and great excitation, presenting the physical manifestations of a broncho-pneumonia, accompanied by profuse expectoration, marked digestive disturbance, loss of appetite, and emaciation, the sputa containing numberless tubercle bacilli. The clinical picture resembles what used to be

called "acute catarrhal phthisis." But among the insane in these cases, so far as I have observed them, the bacilli disappear from the sputa, expectoration ceases, and the patient apparently completely recovers. So far none of these patients have died of tuberculosis, and those who died of tuberculosis had no such outbreak as a part of their clinical history.

Another interesting clinical feature has been the absence of extreme emaciation in a large majority of the cases included in this paper, the loss of weight being comparatively slight, while the course of the disease has been, as a rule, greatly prolonged. On the contrary, in those cases in which the onset of the phthisis has been comparatively sudden and its progress rapid, emaciation has been extreme. There is also a marked difference in the temperature range. In the first class of cases the temperature rarely gets beyond 101° F., while in the latter it frequently goes as high as 105° F., and often does not go below 102° F. until a short time before death, when the usual subnormal excursions occur. The subjective symptoms are also more marked in this latter class of cases. Cough is present, with comparatively profuse expectoration, and the course of the disease is more nearly like what it is among the sane. In the cases in which the course of the disease is prolonged, tubercle bacilli are not abundant and sometimes entirely absent, but staphylococci are always present, and often streptococci and pneumococci; while in the rapidly fatal cases tubercle bacilli are always present in abundance, but the pus-forming bacteria are not so common, and often are entirely absent. Pulmonary hemorrhage did not take place in any of the cases included in this report, and in my experience practically never occurs among the insane.

In the class of cases in which the subjective symptoms are absent and emaciation is slight, death usually occurs as the result of renal inadequacy and pulmonary oedema, and the urine as well as the condition of the heart and arteries indicate a chronic interstitial nephritis; while in the more rapidly fatal cases there is a parenchymatous nephritis, sometimes acute, tubercle bacilli often appearing in the urine abundantly. The two following cases illustrate the types described:

M. C., admitted July 30, 1895. Born in Ireland, thirty-six years old, single, a carpenter by trade. A brother of this patient was admitted about two weeks previous, and both were excited at time of admission. Both parents died in middle life from "lung trouble," a brother, aged fifty-nine years, from "*la grippe*," and a sister, at thirty-five years, after confinement. The patient was healthy as a child, but after he reached adult life suffered from chronic constipation and "kidney disease." About three years previous to coming to the hospital he fell and hurt his head. Since that time he occasionally suffered from pain in the back of his head and neck. This pain was more severe after his mental disturbance began. When admitted he had difficulty in passing his urine and was constipated. He also had a varicocele, numerous dilated veins over the surface of

the lower extremities, and suffered from internal hemorrhoids. He improved rapidly, both physically and mentally, and with his brother left the hospital August 31, 1895.

June 29, 1896, the brothers were readmitted. M. being very much depressed, while the other was exalted. This time he was in very bad physical condition, poorly nourished, and the respiratory sounds were harsh over the apices of both lungs. The urine contained albumin, but no casts. He improved physically but steadily deteriorated mentally, and was persistently depressed, indifferent, and without disposition to occupy himself.

In January, 1897, he began to lose in weight; his appetite became capricious, but his physical condition remained fair, and during the summer he improved and became fairly active. October 14th he was put in bed. There was some elevation of temperature. Respiration and pulse accelerated, and he complained of pain in the chest. There were no definite physical signs present, although there was a harsh respiratory sound over both lungs generally. He improved rapidly and was out of bed in a short time. Temperature normal, appetite and physical condition good.

November 29th he again went to bed, complaining of chills and diarrhoea. He had some cough at night. Temperature, 101° F. The physical examination at this time showed defective resonance over both apices. Sibilant and sonorous râles and breathing high pitched at the bases of both lungs. The sputum contained streptococci and numerous tubercle bacilli. The condition of the lungs became rapidly worse. Diarrhoea developed and tubercle bacilli were found in the feces and urine. A cavity was found in the left upper lobe. The diarrhoea continued. The urine contained both albumin and casts. He failed steadily in weight and strength; the temperature went up to 104° and 105° F., and never got below 102° F. Tubercle bacilli were abundant, and the pus-forming bacteria, especially staphylococci, were present for some time before his death. He died January 24, 1898. A post-mortem could not be obtained.

The brother is living, robust and vigorous; but there is some change in his arteries, and eventually he will die of nephritis.

T. M., admitted April 8, 1890, aged twenty-one years; nativity, Poland; occupation, lumberman. He was a stranger and no information could be obtained concerning his family or personal history, except that he was and had been an inebriate; markedly peculiar and erratic in his conduct always. He was found in a "root cellar," where he had secluded himself for some time, living on the vegetables stored there. He had auditory and visual hallucination, was a victim of religious, with expansive ideas concerning his relations with the Deity, and a marked disposition toward seduction. When in the presence of others he was suspicious, sullen, and irritable, occasionally disposed to be violent.

Examination on admission showed the patient to be in poor physical condition, his vitality very much lowered, and the circulation quite feeble. He improved physically after coming to the hospital, but continued to deteriorate mentally, until within a short time he was stupid, filthy, entirely indifferent to his surroundings, requiring constant personal care. Afterward he became more active, but continued to grow more confused mentally; became entirely demented within the first year of his hospital residence.

There was no material change in his condition until the fall of 1896, when he became more stupid, lost his

appetite, and grew weak physically. He was put in bed December 2d, failed rapidly, and died December 12, 1896.

Necropsy: There was some emaciation, and the muscles were flabby from lack of use. The forearms and legs were oedematous. The changes in the brain and its membranes were characteristic of dementia. The cerebro-spinal fluid was sterile.

The pericardial cavity contained forty cubic centimetres of straw-colored fluid and there were numerous fibrous patches on the visceral layer of the pericardium. The fluid contained tubercle bacilli.

The heart weighed two hundred and thirty-four grammes. There was a large deposit of fat about the apex, but the muscle was firm. The valves were competent.

The right pleural cavity contained eighty-five cubic centimetres of fluid. The lung was generally adherent, with the adhesion most marked at the base. It weighed eleven hundred and fifty-three grammes. The whole lung was fibrous, while nodules and small cavities were scattered throughout its substance, except a small fringe of comparatively healthy tissue at the base anteriorly.

The left pleural cavity contained ninety cubic centimetres of fluid. The lung weighed eleven hundred and forty-seven grammes. It was generally adherent, densely fibrous, and filled with nodules and small cavities.

The organs in the abdominal cavity all showed marked degenerative change, with general fibrosis most marked in the liver and kidneys.

Tubercle bacilli were stained in the lung tissue and fluid from the pleural cavities. The tuberculous infection evidently had been comparatively recent in this case, and the destructive change was slight on account of the extreme fibrosis in the lung tissue.

Post mortem, the difference in the conditions present is just as marked as is the clinical difference. In the cases in which the course of the disease has been comparatively rapid, the changes in the lung are characteristic of disintegration, with destructive change in the parenchyma of the lung, and the formation of large abscess cavities. In the slowly developing cases the changes are degenerative, cavities are small, with dense fibrous walls, and these cavities are most common in the lower lobes and toward the exterior of the lung. The lung is heavy, its tissue dense, and the bases often only a mass of tough fibrous tissue, the only tissue at all resembling the normal lung in the middle and anterior portion of the lung. The resemblance between the changes in these cases and the conditions of the lung tissue in bovine tuberculosis is remarkable. The slow degeneration of the lungs of fifty cows, all of which died of their response to the tubercle bacilli, was found in the lung tissues were present all the changes found here, and the only difference being that the cavities were small and not dense as a result of the extreme fibrosis, abscess cavities, and the destruction of the lung tissue being complete. This resemblance is so marked that I have to study the history of the disease in the cow with tuberculosis for evidence of defective nutrition, and that all the cases with the clinical picture of slowly devel-

oping lung disease, without subjective symptoms, emaciation, or much elevation of temperature, occurred among primary degenerates whose insanity began during adolescence and rapidly lapsed into dementia, and whose existence for varying periods of time had been purely vegetative. Among the cases in which the change was destructive and the course of the disease rapid and accompanied by well-defined subjective symptoms, the opposite conditions obtained, and they were generally cases of unstable brain development, giving way under stress of disease or the exigencies of life. They more nearly correspond with the same in the conditions under which the phthisis develops, its progress, and the nature of the changes found post mortem.

In the animals observed by me tuberculosis rarely presented any outward manifestation of the diseased condition. In one case, in which the lungs weighed thirty-eight pounds and were densely fibroid, with an enormous abscess cavity, the animal was sleek and fat, apparently robust, having a hearty appetite, and giving a large quantity of milk. In others the same conditions were present, only in a lesser degree. Even in the mildest cases tuberculous pleurisy was present, with enlarged bronchial glands and fibrosis of the lung, most marked on the exterior, giving to the surface of the lung the appearance of scale armor. Now this same type of degenerative lung disease occurs among the insane, presenting almost identical clinical and pathological conditions.

There are commonly during the progress of the phthisis absence of pain and dyspnoea, little or no cough or expectoration, no hæmorrhage, and very few symptoms referable to the lungs, our attention being first called to the case by weakness, elevation of temperature, and sweating. The course of the disease in this class of cases is very greatly prolonged, as a rule, and even after the patient is put in bed he may continue a merely vegetative existence for periods varying from three months to a year. After death the changes found resemble greatly those resulting in bovine tuberculosis, being only more advanced, and show that the degenerative changes have been greatly prolonged and probably existed a long time before our attention was called to them by the symptoms produced by infection with the pyogenic bacteria. Again, the apparent absence of the distressful symptoms of phthisis in the demented degenerate makes the analogy more complete by showing how mental reduction tends to bring the nervous organization by retrograde change to the level of the type existing in the lower animals; while a corresponding somatic reduction goes on as the result of the establishment of premature senility.

In some instances in which there was markedly defective organization, the morbid anatomy of the lung was the same as that found as the result of senescence.

The following cases illustrate these changes and the resemblance referred to:

P. L., a man, admitted April 11, 1892; nativity, Canada; age, eighty-four years; senile degenerate. When admitted, this patient was in good condition, with the exception of the presence of a double inguinal hernia. Mentally he was confused, with progressive reduction of capacity. There was no variation in his mental condition during the time of his residence, and very little in his physical status, except occasional attacks of infective diarrhoea, from which he always promptly recovered. The arteries were hard, the heart's action irregular and intermittent, and he often complained of vertigo. The last two months he spent in bed, growing progressively weaker. There was a large area of dulness over the lower portion of the right lung and there was some cough. He died April 18, 1895, presenting the usual manifestations of progressive uræmia.

The changes in the brain were those usual in senility, but there was an unusual amount of arteriosclerosis. The pericardial cavity contained eighteen cubic centimetres of cloudy fluid. The heart muscle was soft and flabby, the endocardium thickened. The leaflets of the tricuspid valve were much shrunken, as were the semi-lunar valves, and both contained numerous calcareous deposits. There were calcareous patches scattered over the other valves also. The heart weighed thirteen ounces.

The right pleural cavity contained thirteen hundred cubic centimetres of thin, purulent fluid, and the pleura was much thickened posteriorly and laterally. The left pleura was adherent at the apex, anteriorly, and to the diaphragm. The right lung weighed twenty-one ounces, and its pleural covering was densely thickened at the base anteriorly and posteriorly and there was some hypostatic congestion. The left lung weighed twenty-six ounces. The apex was deformed by scars externally, and there were nodules and small cavities throughout its structure. Both lungs were deformed externally by numerous old cicatrices, and the lung substance was dense and inelastic. The organs in the abdominal cavity all exhibited marked degenerative change and the pyramidal substance in the kidneys was largely replaced by fat.

M. A. B. S., a woman, admitted April 10, 1872; nativity, Switzerland; age at time of death, seventy years; senile degenerate. This patient is said to have always been "weak-minded" and her condition was that of chronic excitement at the time of her admission. During her residence in the hospital she was in good health, as a rule, and mentally she was demented and quiet.

On February 4, 1896, she complained of severe pain in the left side of the chest. The temperature was elevated from one to two degrees and respiration was accelerated. On the next day a well-marked pneumonia, involving the lower lobe of the left lung and associated with pleurisy, was made out. The patient's strength failed rapidly and she died on February 8th.

The changes in the brain were those characteristic of dementia. The pericardial cavity contained fifteen cubic centimetres of sanguineo-purulent fluid. The heart weighed fourteen ounces. The muscle was thickly covered with fat. The valves were competent. The right ventricle contained a partially organized clot. The left pleural cavity contained a hundred cubic centimetres of fluid, and the lung weighed thirty-five ounces and was universally adherent. The adhesions were old and firmly organized at the apex, but recent over the middle portion and the lower lobe. There was a fibrous exudate over the whole of the lower lobe, more abundant ante-

riorly, and this exudate could be peeled off in sheets. The lung was dense and solid at the apex, where there were some tubercles. The lower lobe was solid throughout. The right pleural cavity contained no fluid. The lung weighed seventeen ounces and was almost universally adherent. The anterior margins were crepitant, but the posterior portions of both lobes were in a condition of hypostatic congestion. The density of both lungs was markedly increased.

The abdominal organs were shrunken and fibrous. The kidneys were very much degenerated, and the pyramidal substance replaced by fat to a large extent. The bladder was empty. *Staphylococci*, *streptococci*, *Bacillus pyocyaneus*, and Fraenkel's pneumococcus were found in the pleural and pericardial fluid, the pneumococcus largely predominating. No tubercle bacilli were found.

T. M., a man; admitted April 8, 1890; nativity, Poland; age at time of death, twenty-six years; a primary degenerate. When admitted, the patient was in poor physical condition on account of exposure and want of food. He was self-depreciative and the victim of religiosity when admitted, but rapidly became demented and stupid. During the last three years he degenerated physically as well as mentally, was put to bed December 2d, and died December 12, 1896. The changes in the brain were those characteristic of dementia. The pericardial cavity contained forty cubic centimetres of fluid, and there were numerous white patches on the visceral surface. The heart weighed seven ounces and a half. There was a large deposit of fat at the apex. The muscle was firm and the valves were competent.

The right pleural cavity contained eighty-five cubic centimetres of fluid. The lung weighed thirty-seven ounces and a half. At the apex there were numerous small cavities, and throughout the lung there were nodules and cavities. The left pleural cavity contained ninety cubic centimetres of fluid. The lung weighed thirty-seven ounces. It was adherent antero-posteriorly. There was a cavity the size of a walnut in the apex and a smaller cavity in the axillary line. This lung was almost entirely solidified and filled with nodules and small cavities. The tissue of the lung was densely fibrous and inelastic. There were tubercle bacilli in the pleural but not in the pericardial fluid. They were also present in the lungs.

The organs in the abdominal cavity showed marked degenerative change with fibrous increase. The kidneys were increased in weight, their capsules adherent, and the cortex much thickened. The mesenteric glands were enlarged, and numerous ulcers existed in the intestine.

A. R., a woman; admitted November 24, 1886; nativity, Sweden; age at time of death, thirty years; primary degenerate. When admitted, the patient had been in sane for two years, and was a victim of sexual excitement. She passed gradually into dementia, becoming stupid and filthy. Her physical condition was fair. In December, 1893, physical signs of tuberculosis became apparent. There was a prolonged remission and one short exacerbation of the disease between this time and March 5, 1895, when the patient went to bed very much prostrated, with profuse expectoration. Tubercle bacilli were found in abundance. She grew steadily weaker, with well marked physical signs, and died April 11, 1895. The changes found in the brain were those of dementia. The pericardial cavity contained twenty-four cubic centimetres of slightly opaque fluid. The heart weighed eight ounces. The aortic valves were incom-

petent, owing to retraction of the leaflets. The leaflets of the other valves were slightly thickened. The mediastinal and bronchial glands were enlarged. In the right pleural cavity there were old and firm adhesions over the upper half of the lung. The lung weighed twenty-eight ounces, and there were nodules and cavities throughout. The lung was a dense fibrous mass, except at the margins anteriorly. The left pleural cavity was almost obliterated. The lung weighed nineteen ounces, and there was cloudy fluid in the numerous cystic cavities formed by the adhesions. The apex of the lung contained a cavity as large as a goose egg, and there were nodules and numerous small cavities throughout the lung. The intervening tissue was a dense fibrous mass. The organs in the abdominal cavity were undergoing progressive degeneration. The kidneys were small, lobulated, but not markedly degenerated.

It has often been a matter of marvel to me, in examining the lungs of some of our patients, how they manage to live so long when there is apparently nothing but the anterior margins of the lobes of the lungs left for them to breathe with.

All variations between the types described are found, as can be seen by referring to the table, and it will be noted that almost as many changes are found in the lungs of those patients who die of nephritis as among those who die of tuberculosis.

Another matter of clinical interest is the fact that the phthisis often exists for a long time before the tubercle bacilli can be found in the sputum, and in some of the cases in which there are well-developed physical signs of phthisis the patients die of intercurrent disease, and show well-marked fibroid change in the lung, but no cavities of tubercle bacilli. In all the cases in which abscess cavities were found, some form of pus-producing bacteria were always present, the most common being the *Staphylococci pyogenes aureus* or *albus*, and Fraenkel's pneumococcus.

To recapitulate: Phthisis among the insane is, in old institutions like the hospital at St. Peter, a proportionately more common cause of death than in general practice outside of the large cities. The death-rate for the last year of the period included in this paper, from this cause, was thirty-two, which is forty-six per cent. of the number of deaths for the year. The disease is most common among primary defectives of the connective-tissue type, to which most epileptics and so-called cases of adolescent insanity belong. After these it attacks most frequently senile cases.

Now, taking into consideration the fact that all patients are practically subjected to the same conditions, all equally exposed to the same sources of infection, why is it that only a certain number of them die of phthisis? A study of the family and life history of those patients who have died of phthisis in this hospital shows that in none of the cases was there any evidence of lung disease at the time of admission to the hospital, or in the family, except that which was concurrent in the same generation. This same result was obtained by me in a

statistical study made in another connection, Insanity and Phthisis, their Transmutation, Concurrence, and Coexistence (*Journal of Nervous and Mental Disease*, October, 1895).

Meigs, in his recently published work on *The Origin of Disease*, says in the chapter on the lungs: "Extensive emphysema and fibrosis or vascular disease may often be found in the bodies of persons who had suffered no attack of sickness while these degenerative conditions had been progressing, but had enjoyed sufficiently good health to be able unimpeded to pursue their ordinary vocations."

In my own experience this is especially true in the bodies of those who have passed middle life. But among the insane I have found these degenerative changes in all defectives, including epileptics, without regard to the period of life, and it is in this class of patients, reaching adult and middle life, that we find such marked destructive and degenerative change in the lungs, where the cause of death has been other than phthisis. Indeed, there is no one thing so characteristic of the somatic changes accompanying degeneration as the excessive formation of connective tissue. I look upon this tendency toward the excessive formation of connective tissue as the manifestation of inherent defect in the structure of the organism, whereby its potentiality is limited, and the conditions of senility occur prematurely as a result, the variation in different individuals being due to the degree of defect and nature of the environment. I have found two general types of defective or unstable structure—the one represented by excessive connective or structural tissue formation and correspondingly imperfect functional development; the other by excessive functional development, with marked instability and the tendency to react extremely to slight stimuli. This type is represented in its most exaggerated form by the children who have convulsions from apparently trivial causes; who are constantly liable to extreme reaction from slight sources of irritation of the respiratory or digestive tract; who show marked signs of instability during the period of second dentition, and, at puberty or during adolescence, die of acute phthisis; who have hysterical outbursts, or become suddenly insane and as suddenly recover. We see this type only very rarely among the patients admitted to this hospital, and they usually recover; so that opportunity for post-mortem study of the nature of the changes in the brain, heart, lungs, and abdominal viscera does not come often. In the cases examined we have found the changes to be very different, and in some cases exactly the opposite of those found in the connective-tissue type. The brain is shrunken and microscopically shows marked disintegration of the cortical cells, without material increase of neuroglial tissue; the organs of the body are small, with destructive or atrophic change, according to the cause of death, the blood-vessels showing destruction of the intima and muscular coat, with only apparent increase of fibrous tissue. The connective-tissue type has been sufficiently

described in the body of the paper, and the case records indicate the nature of the changes found. Of course, these types tend to overlap and run into each other, and are seldom absolutely clearly defined except in childhood and during adolescence. Three such cases were reported by me in the paper before referred to, two being children who died of tuberculous meningitis, the other a young girl who died of miliary tuberculosis. The bulk of our patients belong to the connective-tissue type; the connective-tissue cell, being of a lower order of development than the epithelial or functional cell, would necessarily dominate the structure of a defective organism.

The conclusion I have come to from a careful study of the morbid anatomy of the lungs and abdominal viscera of the insane is that fibrosis is always present in some degree; greatest in the primarily defective, least in the unstable class. In the largest number fibrosis is greatest in the kidney, next in the lungs; the heart being least involved, and for obvious reasons. So far as our records show, all patients who do not die of cerebral hæmorrhage or the acute illnesses of hospital life have for the cause of death pulmonary phthisis or nephritis. In all the cases of nephritis there is more or less degenerative and destructive change in the lungs, and where phthisis is the cause of death the kidneys are also involved. When the habits and mode of life of the average chronic insane patient are considered—the tendency to eat voraciously and take very little exercise, the enforced idleness during the winter, with overcrowding and poor ventilation—it is not surprising that the lungs and kidneys should show the greatest amount of degenerative change; and the converse of this is shown by the good health and freedom from lung disease or degenerative tissue change among those patients who lead an active outdoor life and are steadily occupied with manual labor. Modern physiology teaches us that any irritation of an organ or part will induce not only a determination of blood, with increase of nutrition and function, but also an actual hyperplasia of the connective-tissue framework of the organ. Now the persistence of the irritation or its increase will easily turn the normal into an abnormal process, and we have a hyperplasia that is pathological; an increase of connective tissue sufficient to interfere with function, and the after contraction of which will be the beginning of the process of degeneration. If we are dealing with a defective organism it is easy to see how much smaller an amount of irritation will be required to set up the degenerative change and how much more rapid and extreme will be the fibrosis resulting from the persistence of the hyperplasia. From this the conclusion follows naturally as to the susceptibility of the insane to disease of the lungs; and the constant presence of the means of infection, coupled with the overcrowding of our large State institutions, explains the facility with which our patients become the victims of phthisis, and why degenerative changes in the lung are found practically in all cases.

ON A POLYMORPHOUS CEREBRAL TUMOR

(ALVEOLAR GLIOMA?)

CONTAINING TUBERCLES AND TUBERCLE BACILLI.

By CLARIBEL CONE, M.D.,

PROFESSOR OF PATHOLOGY, WOMAN'S MEDICAL COLLEGE, BALTIMORE.

[From the Pathological Laboratory of the Johns Hopkins University and Hospital.]

THE classification of tumors of the brain and its membranes has been considerably modified since the early days when all such neoplasms were referred to one of the two main tumor groups—to the so-called fibrino-plastic or to the cancerous growths. By improved methods of microscopic technique investigators have still further added to our knowledge of the histological structure and the histogenesis of tumors, so that now, in the light of modern research, the classification of brain tumors must be still further remodeled, and the grouping under each class to a certain extent recast.

In the earliest times all tumors were classified according to their clinical symptoms, and types were recognized mainly as benign and malignant. Later their morphological characteristics were made the criteria for diagnosis. Tumors are now named also according to their histogenesis.

With both histogenesis and morphology ascertained, a mistake in diagnosis is scarcely possible, though additional factors are of value in determining the nature of the growth.

Such definite rules for guidance in the diagnosis of tumors would seem to make a definite classification quite possible. But, as will be seen later, the origin of many tumors is difficult to trace, and the morphology is not always typical in itself of the normal type of tissue from which the tumor springs.

In a general way, then, it may be said that a positive diagnosis can be made only:

1. From histogenesis:—(a) where the initial stage of the developing tumor can be certainly traced, or (b) where the periphery of an older growth shows the transition from normal to atypical structure.

2. From morphology:—where the tumor occurs in an organ not normally possessing elements which could give rise to neoplasms of structure similar to each other if, at the same time, it can be shown whether or not the origin was from embryonic misplacement or from metastatic germs.

In other cases an approximate diagnosis may be formed, but a decisive conclusion can not be reached.

It will thus be seen that any classification of brain tumors which can be made must of necessity be more or less faulty, and that a certain number of tumors will always be referred to classes to which they do not properly belong.

The classification of brain tumors, as given in the various text books on pathology, is more or less un-

form. Such tumors are classified according to their points of origin—(1) from the brain substance, and (2) from the meninges, the choroid plexuses, and the ependymal lining of the ventricles.

The tumors of the brain substance are glioma, together with neuro-glioma; sarcoma, including endothelioma, psammoma, glio-sarcoma (?), and various other mixed forms; cholesteatoma, angioma, fibroma, osteoma, lipoma, dermoid cyst, epithelial growths which may have penetrated the cerebral substance from the choroid plexus or the ependymal lining of the ventricles; and secondary growths, such as sarcoma and carcinoma.

The tumors of the meninges, the choroid plexuses, and the ependymal lining of the ventricles include the various forms of sarcoma, of which the endothelioma (alveolar sarcoma) is by far the most frequent variety; psammoma, cholesteatoma, fibroma, lipoma, chondroma, osteoma, carcinoma (?), echondroma, dermoid cysts, and secondary tumors (carcinoma and sarcoma).

Of these neoplasms the glioma group is peculiar to the central nervous system, arising, as it does, from histological elements found normally in the central nervous system only. It, together with the sarcoma group, forms the most common variety of tumor found in the brain.

The other types of cerebral neoplasm are rare. This is especially true of the epithelial group. But while this fact is founded upon experience, it would seem *a priori* most plausible to believe that neoplasms may often arise from the epithelial lining of the choroid plexuses and of the ventricles, as do similar growths from the other epithelia of the body. The literature, however, has shown this not to be the case, since most of the cerebral neoplasms described as carcinoma and epithelioma are shown, both from description and illustration, to belong to the endothelial group. The cases of Eberth* and Arndt† are certainly examples of this latter type of growth. Rokitsansky's‡ case of "carcinoma" is based on insufficient evidence; Walther Selke's§ description was of a papilloma in which he believed it possible for carcinoma to develop; while the only authentic cases of primary epithelial tumor of the brain which I have found in the literature are those of Ziegler, who reported a case of "carcinoma" originating in the choroid plexus of the third ventricle; of Cornil and Ranvier,¶ who reported a case of "carci-

noma" of the third ventricle which had originated from the ependyma; and a case of von Wunschheim,* in which a primary "carcinoma" of the fourth ventricle was shown to have its origin at the point of transition between the ependymal epithelium and the plexus epithelium.

In view of the general frequency with which glioma and endothelioma occur, and of their possible bearing upon the tumor to be described, the leading characteristics of these two groups may be considered in some detail.

The glioma is by far the most common type of tumor found in the brain, developing, as it does, from the neuroglia. Since the recent researches of Golgi and von Kölliker, and the still later investigations of His, Ramón y Cajal, von Lenhossék, and others, upon the embryology and histology of the normal brain, pathologists have also gained a more intelligible appreciation of abnormal processes. And now, by basing the diagnosis of glioma upon histogenetic as well as upon structural peculiarities, a more ready differentiation of the tumor groups is rendered possible.

It is thus that Stroebe † and other pathologists have applied these facts in their investigations upon glioma and have given a more comprehensive view of the entire subject. By the use of Weigert's and Mallory's differential stains and other improved methods of technique they have added to our knowledge of both the morphology and the histogenesis of glioma. They have shown, at the same time, that many tumors heretofore described as sarcoma, glo-sarcoma, neuro-glioma, etc., are to be included under the simple glioma species.

Stroebe, in his comprehensive monograph, *Ueber Entstehung und Bau der Gehirngliome*, has given a thorough survey of the literature upon glioma from the initial publication of Virchow ‡ up to the time of his own investigation. He has communicated the results of six carefully studied cases of his own, and gives some interesting conclusions. Before going into the details of Stroebe's work upon pathological neuroglia it will be well to consider briefly the prevailing conceptions of normal neuroglia as this tissue is now understood.

The neuroglia is functionally and anatomically the connective tissue of the central nervous system. It was formerly thought to be a mesodermal structure like the other connective tissues of the body, but more recent investigations have shown it to be derived from the ectoderm. In structure it consists of fibres and cells, the fibres being woven into a delicate glistening network, while the cells are small, apparently branched, and are intimately intermingled with the network of fibres. The progenitors of the neuroglia cells are the

embryonic ependymal cells, and probably certain less differentiated elements known as astroblasts. The normal neuroglia thus presents, in the course of its development, mainly three different types of cells—cells of ependymal type; cells of a simple and undifferentiated form, or astroblasts; and the spider and brush cells, or astrocytes.

With regard to the relation of the neuroglia fibre to the neuroglia cell there exists considerable difference of opinion. It was formerly thought that the fibre was a direct protoplasmic outgrowth from the cell body, and Golgi's silver method did much to further this belief. It has since been claimed by Weigert that this relation of fibre to cell holds good only for embryonic forms, while a separation exists in adult cells. This position is made probable by the use of his differential chemical stain, and has been further confirmed by the researches of Mallory and others.

Stroebe, on the other hand, believes that there is insufficient evidence for the acceptance of Weigert's claim, and still adheres to the view of direct continuity of structure for both adult and embryonic forms. And Taylor,* although admitting the "essential correctness" of Weigert's view, takes a position between the two extremes and suggests the existence, even in developed neuroglia, of a certain number of neuroglia elements whose fibres are still in the relation of physical continuity with the cells. His careful researches have led him to conceive of the "evolution of neuroglia from cells without processes to cells with processes, and then to cells whose processes have been completely differentiated into fibres." It is probable that this more conservative position is correct, but that, as Taylor further states, "with all the means at our command the absolute determination of the relation of cells and fibres in individual cases remains difficult and at times impossible."

Stroebe has shown that gliomata of the central nervous system arise from a tissue whose elements take their origin from the neuroglia or from the ependymal cells. In support of this view he cites numerous cases of glioma from the literature; but especially confirmatory is a case of his own in which cavities lined by ciliated cylindrical epithelium were found in the middle of a glioma. In this latter case the pointed extremities of the epithelial-like cells which lined the cavities were drawn out into fine filamentous processes which were intimately interwoven with the surrounding network of neuroglia fibres—all properties analogous to those which belong to the ependymal cells of the ventricles and the neural canal. And because of this analogy Stroebe regards the cavities as abnormal lateral offshoots from the primitive neural canal, which originated in a disturbance of development occurring in the early em-

bryo. That the cavities were no longer in connection with the ventricle he regards as insignificant, in view of the fact that the offshoots must have become more and more deeply situated as development went on, until they were finally shut off from all communication with the primitive canal.

At the time of Stroebe's publication there was but one other case on record in which a cerebral glioma contained cystlike formations with an incomplete lining of cubical epithelial-like cells. This was a case reported by Buchholz,* and resembled Stroebe's case in all essentials except that here the "epithelium" possessed no cilia.

Since the reports of Buchholz and Stroebe there has appeared in the literature, so far as I can find, but one similar case. This was recently reported by Henneberg,† and concerned a cerebral glioma which contained cavities lined with cylindrical "epithelium." Here, as in the case of Buchholz, the cells possessed no cilia.‡

Curiously enough, these three cases, with almost identical anatomical features and representing the entire literature upon this class of cerebral tumors, have been differently interpreted by each of the three observers. Stroebe, as said, regards his case as the result of embryonic misplacement from the primitive neural canal. Buchholz interprets the "epithelium" in his case as transformed glioma cells which, as the derivatives of glia cells, have an ectodermal origin. These glioma cells, he thinks, under certain conditions, such as pressure, may take on an epithelial-like form. Henneberg attributes the epithelial-lined cavities in his case to the outgrowth of gliomatous excrescences into the lateral ventricle, which, as they progressed outward, had left portions of the ependyma deeply sunk in the tumor. These portions subsequently developed into the cavities described. It is probable that all three cases are representative of the same general pathological condition, and that the theory of embryonic misplacement, advanced by Stroebe and bearing out the Cohnheim hypothesis, may be taken to explain them all.

In further support of this theory of histogenesis are numerous other pathological processes of both brain and cord in which epithelial-lined cavities exist, often still maintaining their connection with the ventricle or the central canal. The cavities in these various processes are not always interpreted as the result of embryonic

misplacement by the observers who reported them, but they seem to us conclusive of this view. Such are the many cases of syringomyelia containing epithelial-lined cysts, and the isolated cases of multiple sclerosis (Borst), teratoid tumor (Saxer), hydrocephalus (Henneberg), granular ependymitis (Aschoff), and other cases in which epithelial-lined cavities are found. The literature on this subject has been carefully collected by Stroebe,* and has been still further augmented by Henneberg.†

The structural peculiarities of glioma vary within very wide limits, including all types of neuroglia tissue, both normal and pathological, and all stages of neuroglia formation from the earliest embryonic to the developed adult forms. But while this variation is in itself a peculiarity of the tumor-forming process, there are yet certain leading characteristics by which the glioma may be known. These characteristics include in a general way (a) the presence of stellate neuroglia cells and (b) a fine meshwork of highly refractile fibres which show in most cases a direct connection with the cells. The cells vary in size and shape. Some of them possess numerous fine, short, filamentous processes. Other have coarse, long fibres that are branched. The fibres may be fine or coarse, and the meshwork which they form is loose or dense.

The gliomata are named for the most part according to the element which predominates. Thus, there are fibrous gliomata and cellular gliomata; there are coarse-fibred tumors and fine-fibred forms. There are types of gliomata according to the variety of cell, from the earliest embryonic form to the large ganglion cell-like (neurogliomatous?) element, and there are types in which all transitional forms are found.

According to this nomenclature one finds gliomata classified as fibrous and cellular (Raymond); as spider-celled glioma and brush-celled glioma (Simon); and by Stroebe as small-celled glioma, large-celled glioma, and giant-celled glioma; as cellular (soft) glioma and fibrous (hard) glioma; as star-celled glioma, spindle-celled glioma, polymorphous-celled glioma, and ganglion-celled glioma; as coarse-fibred glioma and fine-fibred glioma; as dense glioma (hard) and loose glioma (soft); and (according to location) as central glioma, peripheral or superficial glioma, and intermediate glioma.

The most recent contribution to the classification of gliomata has been made by Dr. Flexner.‡ In a paper upon Glia and Gliomatosis, read before the Philadelphia Neurological Society, February 28, 1898, he reported a tumor, heretofore undescribed in the literature, to which he gives the name ependyma-celled glioma. It was composed of cells which resembled the ependymal type of cell found in the human embryonic spinal cord.

‡ Since the completion of this paper Rosenthal (Ueber eine eigen thümliche, mit Syringomyelie complicirte Geschwulst des Rückenmark. *Ziegler's Beiträge*, xvi, 1898, 111) has alluded to a tumor of the fourth ventricle, of which he has seen a section, the description of which is to be published by Glucksmann. This will make the fourth case of such tumor reported.

* Stroebe. *Op. cit.* † Henneberg. *Op. cit.*
‡ Flexner. Glia and Gliomatosis. *Ph. Journal of Nervous and Mental Disease*, vol. xxv, 1898, p. 106.

Dr. Flexner classifies gliomata according to their correspondence with certain forms or stages of development of neuroglia, and thus recognizes: (1) tumors made up of cells of simple form corresponding with the astroblast; (2) tumors which contain cells of more complex type corresponding with Deiters's cell, or the astrocyte; and (3) tumors composed of cells resembling the early embryonic ependymal forms.

He further adds that although such a tumor has not yet certainly come to his notice, "it is conceivable that the fully developed or adult ependymal cells may also give rise to tumors whose appearance would be different from the several forms already described.*"

The more or less precise description of the structure of glioma, even though broad in its scope, and the recognition of the genesis of glioma from the ectoderm have, as already said, been made the basis of differential diagnosis for the various tumors of the central nervous system.

Stroobe, in his scheme of differentiation between glioma and sarcoma, lays particular stress upon the close relation of the glia fibre to the glia cell, and upon the peculiar, highly refractile, fibrous network found between the cells. In sarcoma these features are wanting, though there may be occasional cells with processes. Stroobe further considers the mode of growth, and finds that glioma invades the brain as a diffuse infiltration, while sarcoma is usually more or less circumscribed, compressing the brain substance, which, however, it does not infiltrate. In glioma the pial membranes are often intact, or are at most but slightly thickened; in sarcoma they are adherent, forming an integral part of the tumor mass. Medullated nerve fibres are found almost invariably in glioma; in sarcoma, when present at all, they are situated in the periphery. Sarcoma is often associated with mucoid degeneration; glioma shows at most an edematous softening. Where the origin can be traced to the glia on the one hand, or to the connective tissue about the blood-vessels or the membranes on the other, there will, of course, be no difficulty in diagnosis.

While this scheme for differentiation is not generally accepted, it is applicable to a large number of cases.

The diagnosis is difficult for those gliomata alone in which the component cells are mainly astroblasts, since these undifferentiated cells have many features in common with the undeveloped cells of the mesoblastic connective tissue. Indeed, it is impossible at times to

distinguish between the astroblastic glioma and the small round-celled sarcoma, and such tumors have often given rise to the anomalous term *glio-sarcoma*.

The question of the existence of a mixed tumor of the nature of *glio-sarcoma* has been sufficiently discussed in the recent literature, and thus demands but a word of mention. Such a nomenclature is conceded by most of the leading pathologists to be scientifically incorrect as applied to a simple form, since the term as now applied would refer to tumors of mixed epiblastic and mesoblastic origin—that is, to those whose structures are derived in part from neuroglia and in part from the connective tissue of the blood-vessels or meninges of the brain. There is, moreover, according to von Lenhossék, no authentic case of *glio-sarcoma* on record.

It is easy to conceive of this misuse of the term in the early days when Virchow first defined glioma. The glia tumors were then believed to be derived from the mesoderm in the same manner as the simple connective-tissue tumors, and morphological features were made the basis of differentiation. At that time there was no sharp border line between glioma and sarcoma. A very cellular glioma was believed to be a transition stage to the medullary sarcoma, and the choice of a name was voluntary. Now that histogenesis is the primary determining factor in diagnosis, it is surprising that such men as Hanseman,* Henneberg,† and Thoma still adhere to the old method of nomenclature.

It has been seen, however, that these difficulties of nomenclature hold good nowadays for only a limited number of cases. Even where the histogenesis can not be traced it is possible by the application of many different stains to bring out the structural peculiarities of the tumor. The very cellular glioma recently described by Taylor,‡ Henneberg's" cases of glioma with sarcomatous degeneration, and possibly the peculiar cellular tumor described by Alice Hamilton|| as "*neuro-glioma*," would all in former times have been referred to the sarcoma group. And, conversely, it may be said that the recent schemes for the separation of glioma and sarcoma, founded as they are upon both histogenetic and structural differences, would refer most of the so-called sarcomata, *glio-sarcomata*, and *neuro-gliomata* heretofore described to the simple glioma group. This is true of almost all very cellular tumors, which are still interpreted as sarcomata when inadequately studied by the older methods alone.

The endothelioma is the form of tumor most often met with in the internal meninges, and next to glioma

* Roenthal, in the paper previously alluded to, has described a tumor under the name of *neuroepithelioma glomatosum microcysticum*, which shows, among other appearances, typical adult ciliated ependymal cells with processes. This tumor is regarded by the author as having originated from the same embryonic structures that give rise to the central nervous system, but under somewhat different conditions, leading to the formation of an adenomelike tumor structure. He finds in support of this view not only adult ependymal cells, but also these same elements in other stages of development.

is the most frequent variety of neoplasm found in the brain. It may be defined as a tumor of alveolar or tubular structure, which takes its origin from the endothelial cells. The alveolar and the tubular structure may be lost in places through a diffuse proliferation of the growth.

This definition of endothelioma would be very simple if there were complete concurrence of opinion as to what constitutes endothelial cells, if the histogenesis of the tumor could be certainly traced from the endothelial cells, and if the structure of the tumor were uniformly tubular or alveolar. But each of these questions has given rise to much discussion. Indeed, the term endothelioma has been the subject of numerous controversies from its first introduction by Golgi down to the present time. Various views as to its significance are still held by competent observers, some even denying the existence of such a growth. Without entering into these discussions it is worth while only to refer to the early work of Golgi, Waldeyer, and Kolaczek, and the more recent work done by Hansemann,* Ribbert,† von Volkmann,‡ Lubarsch,§ and others who have done much to collect the scattered literature. A brief outline of the more tenable theories may be given. Ziegler,|| in the last edition of his text-book on pathology, defines endothelioma as an organoid sarcoma in which groups and strands of cells result from the proliferation of the endothelium lining the lymph spaces and the lymph vessels. In other words, the endothelioma is a lymphangiosarcoma of alveolar or tubular structure. This definition will be seen to differ somewhat from that expressed in the previous editions of Ziegler's work, excluding as it does from the endothelioma group all new growths which arise from the perithelium covering the blood-vessels, and even such tumors as develop from the endothelium lining the blood-vessels and serous cavities themselves. It thus limits the class of endothelioma to a decidedly smaller group.

A broader definition is that of von Volkmann, who includes among the endotheliomata all neoplasms which arise from the developed endothelial cells, whether these line the blood-vessels, the lymph vessels, the lymph spaces, the serous cavities, or whether they form a flat perivascular covering for the blood-vessels. In the brain it will thus be seen that the endothelioma develops from the endothelium covering the delicate connective tissue trabeculae of the membranes, or it may arise from the perithelium of the cortical blood-vessels.

Where the histogenesis can be traced to the endothelium, as it usually can in the brain, there should be no doubt as to the nature of the growth. Von Jannsen's* case is a typical example of endothelioma traceable to the cerebral membranes, while Carter's† cylindroma may be referred to the blood-vessel sheaths. Where the histogenesis can not be traced to the endothelium the morphology is more or less conclusive, especially in those cases where the type of blood-vessel or lymph vessel with its corpuscular elements is retained. The difficulty still remains where the endothelioma resembles carcinoma, adenoma, simple sarcoma, or, indeed, a combination of the three. The alveoli in such cases may be lined with flat, cuboidal, or cylindrical epithelial-like cells, and may present a variety of degenerations of stroma, of cells, or of both.

Von Volkmann's definition has the advantage of establishing a nomenclature based upon histogenesis alone; and this histogenesis, as clearly indicated, is directly from endothelial cells. It would thus remove from the literature the more or less ambiguous terms which refer to structural peculiarities, and which include both epithelial and endothelial tumors among the present group.‡ Such ambiguous terms are those proposed by Bizzozero, Orth, Klebs, Hansemann, Lubarsch, and others, and include the names angiosarcoma, perithelioma, haemangiosarcoma, lymphangiosarcoma, angiosarcoma endothelioides, cylindroma, endothelioblastoma, and endothelial carcinoma.

For the practical separation of endothelioma and carcinoma von Volkmann's definition is not sufficient, in that endothelium is often not to be distinguished morphologically from epithelium; and the actual origin of the tumor may often be determined only by exclusion. Indeed, Ribbert has shown that the histogenesis of a tumor, even in its peripheral parts, is often not to be recognized with certainty, since endothelioma and epithelioma may give rise to similar microscopic pictures. And what von Volkmann interprets as the transition from the endothelioma cell to the normal flat endothelium of the lymph spaces, Ribbert equally regards as carcinoma penetrating the neighboring tissues in the form of thin, flat epithelial cells.

It is scarcely possible to find sharp differential lines between these two forms of tumor. But Lubarsch§ believes that more may be gained from a careful study of the finer histological structure of the cells than from the histogenesis. Such structural differences he finds

§ Lubarsch. *Op. cit.*

in the coarser granulation of the protoplasm in the cells of epithelial tumors, in their irregular mitoses (Hansmann), in the occasional demonstration of prickles, and in the formation of keratohyalin—features absent from cells of endothelial origin.

What Lubarsch has said of endothelial tumors may be said of tumors in general: "It is wrong to apply only one criterion or but one method of examination in determining the nature of the growth. The more exact the histological examination and the more careful the study of the morphological relations and of the gross anatomical structure, the smaller will be the number of doubtful cases. But even then there must always remain a number of cases as to the nature of which the first authorities can not agree."

(To be continued.)

PUERTO PRINCIPE, CUBA; ITS SANITARY CONDITIONS AND VITAL STATISTICS.

By S. T. ARMSTRONG, M. D., PH. D.,
CHIEF SURGEON, DEPARTMENT OF PUERTO PRINCIPE.

THE city of Santa Maria de Puerto Principe is situated in 21° 20' north latitude, and almost 78° west of the meridian of Greenwich, in the central portion of the province of Puerto Principe, which is in the eastern part of the island of Cuba. Originally the city was located on the north coast, near the place where Columbus landed in 1492; but, in consequence of the depredations of the buccaneers and pirates who made the Gulf of Mexico their cruising ground, it was found necessary to remove the port from the coast to a site some forty-five miles inland, where there was an Indian village, Camaguey, the residence of the cacique. This town was on an undulating prairie that had a dry siliceous soil, and was near the junction of two small streams, the Hatibonico River on the east and south and the Tinima River on the west and south. During the centuries that elapsed since its settlement the town gradually developed into a city that covered some seven hundred and fifty acres; and the population increased from twenty in 1534 to more than sixty-two thousand in 1862. Since the latter date, however, there has been a decrease, and it is believed that there are not more than twenty-five thousand inhabitants at the present time.

While the four hundred years of Spanish occupation have witnessed the constant growth of the place, and are contemporary with the general advance in municipal improvement throughout the civilized world, nevertheless this city has but little to evidence any improvement in the manner of living that is superior to that in vogue in the sixteenth century. The streets are narrow and irregular in their course, and have been laid out without reference to any plan. Some of the principal streets have fair cobble-stone pavements for a part of their course; but many of the streets are unpaved

and the exposed rock or sandy soil constitutes the road-bed. To an extent the streets are the dumping ground for refuse, though this evil does not exist to the extent that prevails elsewhere in Cuba. They are, however, the only channels by which the surface water is disposed of, and it is the rule for house drains to empty into the street. There are no gutters, except such as the heavy rains have worn in the roadbeds, and there is not a sewer in the city.

There is no system of public water supply; while the greater portion of the people use water from wells or cisterns, these sources of supply are sometimes exhausted in the dry season and water is taken from the small stream of the Hatibonico or the Tinima River, which are both likely to be polluted in the vicinity of the city.

The houses are commonly constructed of brick, and as a rule they are but one story in height. Detached residences, that are so familiar in our Southern cities, are unknown. The floor of the house is laid on the ground without any underlying cellar or intervening air space; and there is no ventilation of the space beneath the floor, and no subsoil drainage. It is not surprising, therefore, that the rooms are damp and that diseases prevail that are the usual concomitants of such methods of construction. In the better class of houses these floors are constructed of brick, as wood decays too quickly.

Those rooms of the house that face the street are provided with large unglazed shutters, and similar shutters or doors furnish the light and ventilation for the apartments that open on the interior courtyard that is an indispensable feature of a Cuban house. The rooms are usually spacious, and the high walls and exposed roofs afford a generous cubic capacity. Frequently the rooms communicate by an uninclosed archway, which would make the disinfection of an apartment practically impossible by fumigation.

In the interior courtyard is the cistern or well that supplies the water for the inmates; the cistern is cemented, but the integrity of the materials that form its walls is an uncertain matter. The wells are sometimes cemented for a distance of twelve feet from the surface of the ground; but as a rule they are excavated in the rock, and none of them is above suspicion of seepage.

In some rear room, often adjacent to the open kitchen, is the privy; it is a pit excavated in the rock, and was once cemented, but it is not possible to learn of any one who has ever had such a latrine repaired after its use has once commenced. Sometimes there is a pipe or flue that passes from the pit to the roof so as to afford a means for the escape of the odors and gases. When the odor becomes intolerable, or the pit is filled to overflowing, the contents are removed by manual labor. It is said, on reliable authority, that during the rainy season the saturation of the ground is so great that it is not unusual for these pits to be filled to the brim;

if such is the case, it is apparent that during the dry season there will be an opportunity for the seepage of the liquid contents into the adjacent well or cistern. There were more than five thousand houses in the city in 1879, and, while that number has been reduced in all probability to four thousand buildings at the present time, each of these has its privy, and the filth saturation of the soil that has gone on for years may be appreciated.

There has been in existence a very judiciously arranged code of sanitary laws for the cities of this island, but there is every evidence that they were more honored in the breach than in the observance.

Each householder has been his own scavenger—that is to say, he has had the habit of allowing all refuse, including manure from animals that are kept in a stall in the back part of the house, to accumulate until there is such a mass that it is no longer tolerable, when he has it removed. Fortunately, the limited space in the courts of most of the buildings will not permit a very large accumulation. There has been no system of street cleaning and garbage removal such as would be likely to exist in a properly regulated city in the United States.

The regulation that provided for the registration of deaths seems to have been properly regarded; so these records have been collated for the past five years. These records show that the total annual mortality has increased since 1894, and it is believed that this has been due to the fact that the outbreak of the Cuban revolution resulted in the assignment of a large military force in the city and province, as well as to the policy of depopulation of the rural districts and the segregation of the so-called reconcentrados in the cities, where they could not obtain work or proper food. Such factors would inevitably result in an augmented mortality rate. The deaths recorded were 721 in 1894, 1,699 in 1895, 1,328 in 1896, 1,316 in 1897, and 1,356 in 1898. This increase in the number of deaths, which amounts to more than ninety per cent. more than the total before the revolution commenced, is very significant.

In the department of Puerto Principe there are more than thirty-five hundred United States soldiers stationed, almost half of the command within a short distance of the city. The importance of an investigation of the mortality records is that they serve by their evidence of what have been the principal causes of death to inform us in regard to the diseases that prevail in this locality, and enable those in authority to recommend measures that may serve to diminish the prevalence of such diseases.

One of the questions of paramount interest here, as elsewhere in Cuba, is the prevalence of yellow fever. The local physician assumes that the disease is endemic, and in support of that position is the fact that, except in a few instances, the recorded deaths from that fever, even when it was evidently epidemic, were in persons of Spanish birth. In 1894 there were only twenty-six

deaths from this disease; but consequent upon the advent of troops, many of whom came here direct from Spain, there were six hundred and ninety-six deaths from this fever in 1895. It is estimated that there were seven thousand Spanish soldiers in the city at that time, so the death-rate was about seventy to the thousand of those exposed. It is futile to speculate upon the prevalence of the fever, because there is no record upon which any estimate may be based. But from all available information it is learned that the men were crowded into improvised or other barracks; that they lived in an atmosphere of their own excrement and drank water that was polluted thereby; that their food and clothing was poor, so that they were debilitated and became easy victims to disease; and, when the fever appeared, there was no effort to remove the men to some other place and to disinfect the barracks or its environments. In consequence of the exhaustion of most of the susceptible material, there were but fifty-nine deaths from yellow fever in 1896, and most of these were during the first half of the year. In 1897 there were but three, and in 1898 but two deaths due to this fever. There has been no epidemic of fever since 1895, the number of cases that appeared in 1897 and 1898 are relatively insignificant, and the experience in Santiago, a city that was subject to severe epidemics of this fever, when sanitary principles were applied by General Wood, suggests that attention to what are fundamental principles for the maintenance of health will do much to prevent an epidemic.

The mortality caused by other fevers presents a marked increase in comparison with the year antecedent to the war:

	1894.	1895.	1896.	1897.	1898.
Typhoid fever.....	11	26	15	36	39
Malarial fever.....	1	6	1	1	24
Benign fever.....	19	42	34	50	115
Miscellaneous fevers.....	8	23	21	28	8

The number of deaths due to typhoid fever is not as great as might be expected under the circumstances. Many of those who die of malarial fever acquire the disease on the plantations.

The greatest mortality from any one disease is that caused by tuberculosis. This might be expected in a population that lives in houses built without regard to subsoil drainage or ventilation; where there is no effort to isolate those affected with the disease, or to disinfect apartments or sputa. Tuberculosis caused 141 deaths in 1894, 142 in 1895, 160 in 1896, 188 in 1897, and 181 in 1898. Probably cases of tuberculosis from prison are included in the death-report, but the prison commitments.

Diseases of the intestinal tract caused a large number of deaths annually: 68 in 1894, 188 in 1895, 269 in 1896, 339 in 1897, and 296 in 1898. The insufficiency and poor quality of food, as well as the contami-

nated water supply, are responsible for part of this prevalence.

The infectious principles of tetanus and of glanders seem to be endemic, as there are deaths from these diseases each year.

The accompanying figures give the totals of several classes of disease during the quinquennium 1894 to 1898:

	1894.	1895.	1896.	1897.	1898.
Communicable diseases.....	386	1,263	715	685	759
Diseases of nutrition.....	19	51	113	124	217
" " " the nervous system.....	83	98	128	121	95
" " " circulatory system.....	58	103	157	142	105
" " " respiratory.....	46	49	48	32	31
" " " digestive.....	44	33	41	61	52
" " " genito-urinary.....	19	28	28	19	11
Miscellaneous, etc., diseases.....	66	74	98	131	86
Total.....	721	1,699	1,328	1,315	1,356

During the five years that were included in the investigation, the total mortality in each month showed but slight deviation from the average for the sixty months. If the yellow-fever deaths, which occurred principally during the summer months of 1895, should be excluded because they occurred in soldiers who had just arrived and who did not constitute a part of the native population, then the greater mortality was during the months from December to June.

As elsewhere, the deaths under five years of age exceeded in number the mortality during any other quinquennial age epoch, except during the yellow-fever epidemic of 1895, when the heaviest mortality was during the quinquennium of twenty to twenty-five years.

The commanding general, L. H. Carpenter, who is the military governor of the province, has, since his arrival, done all that he could to better the condition of affairs. But such work has been a matter of difficulty because there has been no money in the provincial treasury, and the only source of revenue is the customs receipts at the port of Nuevitas. A small allotment of funds has been made by the war department for sanitary purposes, and the dirtier streets, the slaughterhouse, and some similar places are undergoing cleansing. As it is believed that the condition of the privies has much to do with the prevalence of disease, and the poverty of the municipality and of its inhabitants precludes the possibility of the construction of sewers, the immediate needs of this sanitation will be met by means of the pneumatic odorless excavating apparatus.

That a public water supply is essential is also recognized, but there are no funds available for the construction of an aqueduct from the nearest source for an ample supply; so an effort will be made to remedy this want by boring artesian wells.

When there is betterment in the two important factors of municipal hygiene, a plentiful supply of water and the removal instead of the storage of excrement, much will have been accomplished; but it will be a

matter of difficulty to instill in the inhabitants those principles of cleanliness and of sanitation that will be necessary to make the beautiful province of Camaguey one of the garden spots of the earth. It is intended to make a house-to-house inspection, employing Cuban physicians who will make reports in regard to the sanitary needs of the domicile; and if the owner is financially able to undertake the improvements required, he will have to make them; but if he is unable, then the municipality must do what is necessary.

It is to be hoped that, if nothing else accrues from the occupation of Cuba by the United States, at least there will be the accomplishment of those sanitary reforms that will terminate the conditions which have made the island a constant menace to us during this century. The military authorities, and particularly the surgeon-general, are duly appreciative of the great responsibility, and through the medical corps are undertaking such sanitary reforms as are likely to further the health of the native population, and thus lessen the exposure of troops that must be stationed here.

THE POST-PARTUM MANAGEMENT OF UTERINE DISPLACEMENTS.*

By EUGENE COLEMAN SAVIDGE, M.D.,

ATTENDING GYNÆCOLOGIST TO ST. MARK'S HOSPITAL;
ASSISTANT GYNÆCOLOGIST TO ROOSEVELT HOSPITAL,
OUT-PATIENT DEPARTMENT.

GENTLEMEN OF THE SLOANE MATERNITY ALUMNI SOCIETY: Your president has asked me to stimulate a discussion by stating my convictions upon this subject.

I have earnest convictions upon it. Most of them have already been published and discussed by the profession. For the purpose of stirring debate, therefore, I shall cite them as published, fully recognizing the lack of modesty which permits an author to quote from himself. These convictions are about as follows:

First. All post-partum displacements are of the same general nature.

Second. The question of their prevention is one of the gravest importance, having a bearing upon longevity itself.

Third. In some few cases, "no matter what you do," the womb will obstinately remain displaced.

Fourth. Trusting any post-partum case to Nature is the wrong thing to do.

Fifth. Doing the right thing will obviate most of the displacements and rob those that persist of their danger.

Sixth. There is a right thing to do.

Post-partum displacements may be to the sides or to the rear and downward. I do not believe a forward post-partum displacement is pathological. But the downward, lateral, and retrodisplacements are all from

* Read before the Sloane Maternity Alumni Society, January 27 1899.

the same cause—namely, enfeebled muscular power—measures for the improvement of which must be applied in early pregnancy, or before conception. Even subinvolution, the most prolific cause of displacement, does not occur where there are no retained secundines and the muscular vitality of the patient is good; so that we must look behind the subinvolution to the muscular debility. It likewise goes without saying that a laceration permitting a prolapse does so because the muscles are impaired and enfeebled. Overstretching the perineal muscles by prolonging the second stage of labor to avoid laceration is another cause of enfeebled muscular power. Frequently, to make good records, we allow this overstretching, and, though our statistics may not suffer, the woman does. Her perineal muscles thenceforward are really dilated muscles, no more capable of fulfilling function properly than the dilated heart.

Therefore, with laceration there is muscular enfeeblement, and without laceration there may be muscular enfeeblement. For this reason I have maintained, in the face of some obstetrical derision, that a frank laceration—assuming careful, successful suturing—is better than a functionless muscle which is often left untoned. For the same reason I insist upon a stitch for the smallest perineal laceration. And I think we have here a most important factor in preventing post-partum displacements.

Regarding the importance of treating and preventing post-partum displacements, I have written (see *New York Medical Journal*, December 25, 1897):

"This malady (of uterine displacement) is the most prevalent ill among women; it contains a sure future menace; all measures for its relief, operative or otherwise, are unsatisfactory; and, most important of all, it can be largely prevented when both laity and profession appreciate its frequency, its gravity, our limitations in coping with it, and the ease with which it can be prevented in most cases.

"The trouble in getting rid of the malady hardly compares with the danger of neglecting it. I shall not speak of the immediate harrowing symptoms; they are blessed if they force a woman to a cure. I pass, too, the aggravation of the pelvic trouble by neglect, and speak of the insidious robbery of the last decades of life that results.

"I have been strongly impressed with the frequency of renal insufficiency and lithæmia in pelvic diseases of women, especially our subject malady, and I am glad that men like Mann, of Buffalo, and Etheridge, of Chicago, are calling attention to it. These patients, because of the predominant uterine symptoms, are seen only by the gynecologist during the period when the insidious vital changes can be checked.

"My argument is that muscular and vital debility brings about this malady; conversely, that this malady brings about muscular and vital debility; and that this reciprocal relation—this malady of passive congestion and engorged venous system—leads to cardiac, renal, and arterial changes that materially shorten life."

As obstetricians we know that there is a mysterious connection between the pelvic congestion of pregnancy

and the dreaded eclampsia; we have theories but no positive knowledge why pregnancy should throw out into menacing prominence renal trouble never before suspected.

My third conviction is that the womb will remain displaced in some cases in spite of all that can be done. I have been severely criticised for pointing out to a scientific body, practically in executive session, the feebleness of our resources in regard to uterine displacement. I still question the expediency—to say nothing of the honesty—of claiming infallibility in medicine. I still think it aids progress to study the disadvantages of our favorite device. I therefore freely confess that some of my most important maternity cases, in spite of all that could be done, have ended with displacements. I have seen displacements follow the work of some of the best men in the city. Moreover, I have seen, and others have told me of, cases of displacements moored to the abdominal wall by the best men in the country, in which the womb had far better have been adrift in the pelvis. Although it was anchored up, or forward, in ideal theoretical position, the symptoms—in these few exceptional cases—have proclaimed that the womb was still displaced from its position of ease, whatever may have been its anatomical relation.

I am convinced that we can no more prevent some displacements than we can prevent lacerations of the neck of the womb. If we dislike to admit this as a professional limitation we can charge it to Nature, who certainly seems to have erred in these two regards.

And this leads naturally to my fourth conviction, which is an intense one. Trusting post-partum cases to Nature is the wrong thing to do. And, moreover, "meddlesome midwifery"—so called—is the only midwifery a scientific man should deign to practise. This ignorant horror of "interfering with Nature" is on a par with spitting on the garment hem to exorcise evil spirits from the newborn, which I have seen practised by the reverential of certain calibre. In the *North American Review* of February, 1897, I wrote upon this subject:

"Considering Nature's marvelous care of her children, the popular reverence for her is not strange. Yet, contrast the bitterness of the wild fruit with the sweetness of the cultivated; the hedge corner wild rose with the American Beauty; the knotty prairie horse with the lithe-limbed thoroughbred. Contrast the adult mouth in which dentistry has not 'interfered with Nature'—the mouth full of tooth cavities, snags, and abscesses—with that full of sound, white teeth saved from decay. If it were as patent that blood vessels rotted and I here add post-partum engorgement and displacements as is inevitable as tooth decay, and as lost as remediable when taken in time—who among the medical would not avoid it?"

Let us as medical men follow this contrast further. Consider the coarse, thick, fat of the country fowl, his clumsy muscles and cloddy flesh, his clubbed nails, his

lengthened intestines—for the intestines of the herbivorous Russian peasant are some feet longer than the intestines of those who live on better prepared and more concentrated food. Put such a sluggard by the side of the trained athlete, whose finely wrought muscles answer to his will as quickly as the violinist's fingers run the scale. Then, see what happens when man, with scientific precision, "interferes with Nature"—which is just the work modern civilization is doing.

If, therefore, a certain sort of food modifies the length of the intestines by several feet, we can easily deduce what modification the ligaments which support the womb undergo when forced to carry the post-partum organ twice or thrice its normal size. We know, however, without deduction that the ligaments do stretch greatly.

Now, the womb rarely returns to normal size before the sixth or eighth week. Note definition of the puerperium in *Gould's Medical Dictionary*: "The period from birth to the time when the uterus has regained its normal size." I have watched this very carefully in a number of women, and have seen in the perfectly clean womb of a non-nursing mother involution delayed as late as the third month. When the puerperium ends is a question of fact and not of dates. Therefore, when a woman walks around with a subinvolved womb, the heavy organ will undoubtedly stretch its supporters—sometimes temporarily, but often permanently—and then a displacement of one kind or another results.

The sogginess of the subinvolved womb leads to another menace, that of sepsis, closely related to our subject. I quote from my paper, *The Feminine Element* (see *New York Medical Record*, March 19, 1898):

"The classic time for making the last visit (in cases of childbirth) is the tenth day. The woman, as a rule, is left to Nature from this time on. Considering the post-*puerperal* engorgement of the womb and the fact that involution is rarely complete before the sixth week, and reflecting upon the gravity of subinvolution in the light of the resident germ, the writer requests the judgment of the profession upon the advisability of establishing a routine of observation of these patients from the classic tenth day to the time of complete involution."

My next conviction is that post-partum care will prevent many displacements, will correct more, and will relieve the symptoms from those that persist. But in order to be allowed to bestow post-partum care we must enlighten the laity. They now fully understand the importance of preventing the spread of contagious diseases. And, to reiterate the dental analogy, they likewise anticipate tooth decay, because they know it is inevitable. As a consequence, alveolar abscesses and rotten teeth are rare with Americans, but very frequent in France, for example, where dentistry is still an American specialty, and the populace "do not interfere with Nature." I believe we can teach patients to criticize the doctor who dismisses them on the tenth day of the puerperium to

the irresponsible care of Nature. I quote again from my paper on Retrodeviations of the Uterus:

"If patients will let us keep them well rather than patch them ineffectually when sick, we can take them to maternity in good vitality. The appearance of the veins in the hands, neck, temples, legs, will tell us what is happening to the veins in the broad ligament. We can relieve abdominal pressure from gas and ptosis by bandages and internal antiseptics; we can stir up the sluggish circulation; we can prevent constipation.

"In childbed we can keep them out of an exclusively dorsal position; we can even turn them face downward occasionally, and teach them that they are ready to get up only when the womb has involuted regardless of tradition. We can curette promptly when necessary, and insist upon the immediate repair of damaged tissue. And, finally, as routine, we can begin tamponing under the heavy uterus from the tenth day, giving ergot, iron, or digitalis when necessary."

The tampon, carrying its medication, reduces the engorgement, supports the heavy organ, and stimulates involution. It is strongly urged in every case where the patient will permit it. Once begun, the patient is the best witness to its efficacy.

Lacerations at the neck of the womb delay involution, and thus aid post-partum displacements. My convictions on this subject are found in my paper on *The Temptation of Skill*, recently read before the Obstetrical Section of the New York Academy of Medicine, viz.:

"Lacerations at the neck of the womb have occasioned much hard feeling in the profession, and have given rise to many misunderstandings among patients.

"The profession would do well to enlighten women about lacerations at the neck of the womb. We should explain why it is beyond our power to prevent them, and why there is even no practical device known to the profession for so doing. We should teach that many will heal spontaneously if attention is paid to them during the months following confinement; that it is by no means settled as wisdom to sew them at the time of confinement; that the doctor who tells a patient with such trouble that she was 'neglected in confinement' is either dishonest or means that the patient neglected herself after she dismissed her obstetrician by failing to have local attention.

"If women were so enlightened it would be less easy for a contemptible medical thief to poison the mind of a patient against the man who carried her conscientiously through a wearisome confinement. Nor would it be deemed a confession of bungling to tell of a laceration needing attention. Then all might receive attention; fewer would require operation; none need be passed silently to avoid criticism.

"Such lacerations may bring catarrh, metritis, sterility, nervous troubles, tubal involvement, uterine displacement, and pelvic congestion. *And how often is this condition, which is a progressive development made possible by the patient's neglect of herself, charged years afterward to the carelessness of the obstetrician!*

"A soggy, subinvolved womb will swell at times as much out of shape as a dropsical leg or abdomen; and a nick that would otherwise heal and leave no more trace than a shaving wound of the face is thereby exaggerated, rendered indolent, and made to granulate into

a scar. Lack of attention to the womb during the three months following confinement is where the neglect occurs. This point can not be accented too strongly. When women know it, and act on the knowledge, trachelorrhaphy will be practically banished from gynaecology, and operations for retrodeviation rare events."

These convictions, expressed in the past, have been made stronger by increasing experience, and I can only reiterate them.
